

SEVENTH EDITION

Scott-Brown's Otorhinolaryngology, Head and Neck Surgery

VOLUME 1

Edited by

Michael Gleason

George G Browning, Martin J Burton, Roy Clarke, John E Elbert,
Nicholas S Jones, Valerie J Lund, Linda M Luxon, John C Watkinson

Scott-Brown's Otorhinolaryngology, Head and Neck Surgery

Scott-Brown's Otorhinolaryngology, Head and Neck Surgery

7th edition

Lead editor: Michael Gleeson

Volume 1

- Part 1 Cell biology, edited by Nicholas S Jones
- Part 2 Wound healing, edited by Nicholas S Jones
- Part 3 Immunology, edited by Nicholas S Jones
- Part 4 Microbiology, edited by Nicholas S Jones
- Part 5 Haematology, edited by Nicholas S Jones
- Part 6 Endocrinology, edited by Nicholas S Jones
- Part 7 Pharmacotherapeutics, edited by Martin J Burton
- Part 8 Perioperative management, edited by Martin J Burton
- Part 9 Safe and effective practice, edited by Martin J Burton
- Part 10 Interpretation and management of data, edited by Martin J Burton
- Part 11 Recent advances in technology, edited by Martin J Burton
- Part 12 Paediatric otorhinolaryngology, edited by Ray Clarke

Volume 2

- Part 13 The nose and paranasal sinuses, edited by Valerie J Lund
- Part 14 The neck, edited by John Hibbert
- Part 15 The upper digestive tract, edited by John Hibbert
- Part 16 The upper airway, edited by John Hibbert
- Part 17 Head and neck tumours, edited by John Hibbert

Volume 3

- Part 18 Plastic surgery of the head and neck, edited by John C Watkinson
- Part 19 The ear, hearing and balance, edited by George G Browning and Linda M Luxon
- Part 20 Skull base, edited by Michael Gleeson
- Index
- CD-ROM

George G Browning MD FRCS

Professor of Otorhinolaryngology, MRC Institute of Hearing Research, Glasgow Royal Infirmary, Glasgow, UK

Martin J Burton MA DM FRCS

Senior Clinical Lecturer, University of Oxford; and Consultant Otolaryngologist, Oxford Radcliffe NHS Trust Oxford, UK

Ray Clarke BSc DCH FRCS FRCS (ORL)

Consultant Paediatric Otolaryngologist, Royal Liverpool University Children's Hospital, Alder Hey, Liverpool, UK

Michael Gleeson MD FRCS

Professor of Otolaryngology and Skull Base Surgery, Institute of Neurology, University College London; and Consultant, Guy's, Kings and St Thomas' and the National Hospital for Neurology and Neurosurgery, London UK; and Honorary Consultant Skull Base Surgeon, Great Ormond Street Hospital for Sick Children, London, UK

John Hibbert ChM FRCS

Formerly Consultant Otolaryngologist, Department of Otolaryngology, Guy's Hospital, London, UK

Nicholas S Jones MD FRCS FRCS (ORL)

Professor of Otorhinolaryngology, Queen's Medical Centre, University of Nottingham, Nottingham UK

Valerie J Lund MS FRCS FRCS (Ed)

Professor of Rhinology, The Ear Institute, University College London, London, UK

Linda M Luxon BSc MBBS FRCP

Professor of Audiovestibular Medicine, University of London at University College London, Academic Unit of Audiovestibular Medicine; and Consultant Physician, National Hospital for Neurology and Neurosurgery; and Honorary Consultant Physician, Great Ormond Street Hospital for Children, London, UK

John C Watkinson MSc MS FRCS (Ed, Glas, Land) DLO

Consultant Head and Neck and Thyroid Surgeon, Department of Otorhinolaryngology/Head and Neck Surgery, Queen Elizabeth Hospital, University of Birmingham NHS Trust, Birmingham, UK

Scott-Brown's Otorhinolaryngology, Head and Neck Surgery

Apart from any use permitted under UK copyright law, this publication may only be reproduced, stored or transmitted, in any form, or by any means with prior permission in writing of the publishers or in the case of reprographic production in accordance with the terms of licences issued by the Copyright Licensing Agency. In the United Kingdom such licences are issued by the Copyright Licensing Agency: Saffron House, 6-10 Kirby Street, London EC1N 8TS

Whilst the advice and information in this book are believed to be true and accurate at the date of going to press, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. In particular (but without limiting the generality of the preceding disclaimer) every effort has been made to check drug dosages; however it is still possible that errors have been missed. Furthermore, dosage schedules are constantly being revised and new side-effects recognized. For these reasons the reader is strongly urged to consult the drug companies' printed instructions before administering any of the drugs recommended in this book.

Contents

Contributors	xi
Preface	xxix
How to use this book	xxxix
Abbreviations	xxxiii

PART 1 CELL BIOLOGY – EDITED BY NICHOLAS S JONES	1
---	----------

1	Molecular biology	3
	<i>Michael Kuo and Richard Irving</i>	
2	Genetics	15
	<i>Karen P Steel</i>	
3	Gene therapy	23
	<i>Scott M Graham and John H Lee</i>	
4	Mechanisms of anticancer drugs	34
	<i>Sarah Payne and David Miles</i>	
5	Radiotherapy and radiosensitizers	47
	<i>Stewart G Martin and David AL Morgan</i>	
6	Apoptosis and cell death	56
	<i>Michael Saunders</i>	
7	Stem cells	66
	<i>A John Harris and Archana Vats</i>	

PART 2 WOUND HEALING – EDITED BY NICHOLAS S JONES	85
--	-----------

8	Soft and hard tissue repair	87
	<i>Stephen R Young and Melissa Calvin</i>	
9	Skin flap physiology	110
	<i>A Graeme B Perks</i>	
10	Biomaterials, tissue engineering and their applications	118
	<i>Colin A Scotchford, Matthew Evans and Archana Vats</i>	

PART 3 IMMUNOLOGY – EDITED BY NICHOLAS S JONES	131
---	------------

11	Defence mechanisms	133
	<i>Ian Todd and Richard J Powell</i>	
12	Allergy: basic mechanisms and tests	144
	<i>Stephen R Durham and Graham Banfield</i>	

13	Evaluation of the immune system <i>Elizabeth Drewe and Richard J Powell</i>	167
14	Primary immunodeficiencies <i>Elizabeth Drewe and Richard J Powell</i>	174
15	Rheumatological diseases <i>Adrian Drake-Lee</i>	183
PART 4 MICROBIOLOGY – EDITED BY NICHOLAS S JONES		193
16	Microorganisms <i>Vivienne Weston</i>	195
17	Viruses and antiviral agents <i>Paul Simons and Karl G Nicholson</i>	204
18	Fungi <i>Juliette Morgan and David W Warnock</i>	213
19	Antimicrobial therapy <i>Vivienne Weston</i>	228
20	HIV and otolaryngology <i>Thomas A Tami and Jahmal A Hairston</i>	238
PART 5 HAEMATOLOGY – EDITED BY NICHOLAS S JONES		251
21	Blood groups, blood components and alternatives to transfusion <i>Fiona Regan and Ian Gabriel</i>	253
22	Haemato-oncology <i>Clare Wykes and Fiona Regan</i>	265
23	Haemostasis: normal physiology, disorders of haemostasis and thrombosis and their management <i>Fiona Regan</i>	278
PART 6 ENDOCRINOLOGY – EDITED BY NICHOLAS S JONES		293
24	The pituitary gland: anatomy and physiology <i>John Hill</i>	295
25	The pituitary: imaging and tests of function <i>Alan P Johnson, Swarupsinh Chavda and Paul Stewart</i>	303
26	The thyroid gland: anatomy and physiology <i>Julian A McGlashan</i>	314
27	The thyroid gland: function tests and imaging <i>Susan Clarke</i>	327
28	The thyroid: nonmalignant disease <i>Lorraine M Albon and Jayne A Franklyn</i>	338
29	The parathyroid glands: anatomy and physiology <i>Mateen H Arastu and William J Owen†</i>	367
30	Parathyroid function tests and imaging <i>David Hosking</i>	379
31	Parathyroid dysfunction: medical and surgical therapy <i>E Dinakara Babu, Bill Fleming and JA Lynn</i>	387
32	Head and neck manifestations of endocrine disease <i>Jonathan M Morgan and Thomas McCaffrey</i>	398

PART 7 PHARMACOTHERAPEUTICS – EDITED BY MARTIN J BURTON	405
33 Drug administration and monitoring <i>Geraldine Gallagher</i>	407
34 Corticosteroids in otolaryngology <i>Niels Mygind and Jens Thomsen</i>	418
35 Drug therapy in otology <i>Wendy Smith and Martin Burton</i>	429
36 Drug therapy in rhinology <i>Wendy Smith and Grant Bates</i>	436
37 Drug therapy in laryngology and head and neck surgery <i>Wendy Smith and Rogan Corbridge</i>	446
PART 8 PERIOPERATIVE MANAGEMENT – EDITED BY MARTIN J BURTON	455
38 Preparation of the patient for surgery <i>Adrian Pearce</i>	457
39 Recognition and management of the difficult airway <i>Adrian Pearce</i>	467
40 Adult anaesthesia <i>Andrew D Farmery and Jaideep J Pandit</i>	488
41 Paediatric anaesthesia <i>Alistair Cranston</i>	507
42 Adult critical care <i>Gavin G Lavery</i>	526
43 Paediatric intensive care <i>Helen Allen and Rob Ross Russell</i>	542
PART 9 SAFE AND EFFECTIVE PRACTICE – EDITED BY MARTIN J BURTON	549
44 Training, accreditation and the maintenance of skills <i>Paul O'Flynn</i>	551
45 Communication and the medical consultation <i>Damian Gardner-Thorpe and Richard Canter</i>	559
46 Clinical governance: Improving the quality of patient care <i>Debbie Wall, Patrick J Bradley and Aidan Halligan</i>	568
47 Medical ethics <i>Katherine Wasson</i>	581
48 Medical jurisprudence and otorhinolaryngology <i>Maurice Hawthorne and Desmond Watson</i>	594
PART 10 INTERPRETATION AND MANAGEMENT OF DATA – EDITED BY MARTIN J BURTON	613
49 Epidemiology <i>Jan HP van der Meulen and David A Lowe</i>	615
50 Outcomes research <i>Iain RC Swan</i>	633
51 Evidence-based medicine <i>Martin J Burton</i>	645
52 Critical appraisal skills <i>Martin Dawes</i>	649

PART 11 RECENT ADVANCES IN TECHNOLOGY – EDITED BY MARTIN J BURTON	673
53 Functional magnetic resonance imaging: Principles and illustrative applications for otolaryngology <i>Paul M Matthews</i>	675
54 Positron emission tomography and integrated PET/computed tomography <i>Wai Lup Wong</i>	684
55 Image-guided surgery, 3D planning and reconstruction <i>Ghassan Alusi and Michael Gleeson</i>	701
56 Ultrasound in ear, nose and throat practice <i>Keshthra Satchithananda and Paul S Sidhu</i>	711
57 Interventional techniques <i>James V Byrne</i>	731
58 Laser principles in otolaryngology, head and neck surgery <i>Brian JG Bingham</i>	742
59 Electrophysiology and monitoring <i>Patrick R Axon and David M Baguley</i>	748
60 Optical coherence tomography <i>Mariah Hahn and Brett E Bouma</i>	755
61 Contact endoscopy <i>Mario Andrea and Oscar Dias</i>	762
PART 12 PAEDIATRIC OTORHINOLARYNGOLOGY – EDITED BY RAY CLARKE	769
62 Introduction <i>Ray Clarke</i>	771
63 The paediatric consultation <i>Ray Clarke and Ken Pearman</i>	776
64 ENT input for children with special needs <i>Francis Lannigan</i>	783
65 Head and neck embryology <i>T Clive Lee</i>	792
66 Molecular otology, development of the auditory system and recent advances in genetic manipulation <i>Henry Pau</i>	811
67 Hearing loss in preschool children: screening and surveillance <i>Kai Uus and John Bamford</i>	821
68 Hearing tests in children <i>Glynnis Parker</i>	834
69 Investigation and management of the deaf child <i>Sujata De, Sue Archbold and Ray Clarke</i>	844
70 Paediatric cochlear implantation <i>Joseph G Toner</i>	860
71 Congenital middle ear abnormalities in children <i>Jonathan P Harcourt</i>	869
72 Otitis media with effusion <i>George Browning</i>	877
73 Acute otitis media in children <i>Peter Rea and John Graham</i>	912

74	Chronic otitis media in childhood <i>John Hamilton</i>	928
75	Management of congenital deformities of the external and middle ear <i>David Gault and Mike Rothera</i>	965
76	Disorders of speech and language in paediatric otolaryngology <i>Ray Clarke and Siobhan McMahon</i>	990
77	Cleft lip and palate <i>Chris Penfold</i>	996
78	Craniofacial anomalies: genetics and management <i>Dean Kissun, David Richardson, Elizabeth Sweeney and Paul May</i>	1019
79	Vertigo in children <i>Gavin AJ Morrison</i>	1040
80	Facial paralysis in childhood <i>SS Musheer Hussain</i>	1052
81	Epistaxis in children <i>Ray Clarke</i>	1063
82	Nasal obstruction in children <i>Michelle Wyatt</i>	1070
83	Paediatric rhinosinusitis <i>Glenis Scadding and Helen Caulfield</i>	1079
84	The adenoid and adenoidectomy <i>Peter J Robb</i>	1094
85	Obstructive sleep apnoea in childhood <i>Helen M Caulfield</i>	1102
86	Stridor <i>David Albert</i>	1114
87	Acute laryngeal infections <i>Susanna Leighton†</i>	1127
88	Congenital disorders of the larynx, trachea and bronchi <i>Martin Bailey</i>	1135
89	Laryngeal stenosis <i>Michael J Rutter and Robin T Cotton</i>	1150
90	Paediatric voice disorders <i>Ben Hartley</i>	1167
91	Juvenile-onset recurrent respiratory papillomatosis <i>Michael Kuo and William J Primrose</i>	1174
92	Foreign bodies in the ear and the aerodigestive tract in children <i>A Simon Carney, Nimesh Patel and Ray Clarke</i>	1184
93	Tracheostomy and home care <i>Michael Saunders</i>	1194
94	Cervicofacial infections in children <i>Ben Hartley</i>	1210
95	Diseases of the tonsil <i>William S McKerrow</i>	1219
96	Tonsillectomy <i>William S McKerrow and Ray Clarke</i>	1229
97	Salivary gland disorders in childhood <i>Peter D Bull</i>	1242
98	Tumours of the head and neck in childhood <i>Fiona B MacGregor</i>	1251

99	Branchial arch fistulae, thyroglossal duct anomalies and lymphangioma <i>Peter D Bull</i>	1264
100	Gastro-oesophageal reflux and aspiration <i>Haytham Kubba</i>	1272
101	Diseases of the oesophagus, swallowing disorders and caustic ingestion <i>Lewis Spitz</i>	1282
102	Imaging in paediatric ENT <i>Neville Wright</i>	1295
103	Medical negligence in paediatric otolaryngology <i>Maurice Hawthorne</i>	1305

Please note: The table of contents for all three volumes can be found on the *Scott-Brown* website at: www.scottbrownENT.com.

The index for all three volumes is included in Volume 3.

Contributors

Victor J Abdullah MBBS FRCS (Eng) FRCS (Edin)

Consultant, Department of ENT
United Christian Hospital; and
Chief of Service in ENT
Kowloon East Cluster, Hospital Authority; and
Honorary Clinical Associate Professor
Department of Otorhinolaryngology, Head and Neck Surgery
The Chinese University of Hong Kong
Shatin, Hong Kong

Jose M Acuin MD MSc

Professor in Otolaryngology–Head and Neck Surgery
De La Salle Health Sciences Campus
Dasmarinas, Cavite, Philippines

Richard Adamson MB BS FRCS

Consultant Otolaryngologist/Head and Neck Surgeon
Fife Hospitals NHS Trust
Scotland, UK

David Albert FRCS

Lead clinician
Department of Otolaryngology
Hospital for Sick Children
Great Ormond Street
London, UK

Lorraine M Albion MSc MRCP

Consultant Endocrinologist and Acute Physician
Queen Alexandra Hospital
Portsmouth, UK

Helen Allen MBChB MRCP MRCPCH

Specialist Registrar in Paediatrics
Addenbrookes Hospital
Cambridge, UK

Ghassan Alusi PhD FRCS (ORL–HNS)

Consultant Otolaryngologist
ENT Department
Barts and the London NHS Trust
London, UK

Mario Andrea MD PhD

Professor and Chairman
Department of Otolaryngology, Voice and Communication
Disorders
Faculty of Medicine of Lisbon
Lisbon, Portugal

Jawaher Ansari MBBS MRCP FRCR

Specialist Registrar in Clinical Oncology
Queen Elizabeth Hospital
Birmingham, UK

Mateen H Arastu MBBS BSc MRCS (Eng)

Specialist Registrar in Trauma and Orthopaedic Surgery
South West Thames Region, UK

Sue Archbold MPhil

Education Co-ordinator
The Ear Foundation
Nottingham, UK

Stig Arlinger PhD

Professor of Technical Audiology
Department of Clinical and Experimental Medicine
Division of Technical Audiology
Linköping University
Linköping, Sweden

Marcus Atlas

Professor of Otolaryngology
University of Western Australia; and
Director, Ear Science Institute Australia
Sir Charles Gairdner Hospital
Nedlands, Western Australia

Patrick R Axon MD FRCS (ORL–HNS)

Consultant Otolaryngologist and Skull Base Surgeon
Department of Otolaryngology
Cambridge University Hospitals
Cambridge, UK

E Dinakara Babu MS FRCS (Eng) FRCS (Ire) FRCS (Glas) FRCS (Inter collegiate) Diploma
in Laparoscopy (France)

Consultant and Clinical Head
Breast and Endocrine Surgery
Hillingdon Hospital
Uxbridge, UK

Claus Bachert MD PhD

Department of Oto-Rhino-Laryngology
Ghent University Hospital
Ghent, Belgium

Lydia Badia FRCS (ORL-HNS)

Consultant ENT Surgeon
Rhinology and Facial Plastics
Royal National Throat, Nose and Ear Hospital
London, UK

Jose V Sebastian Bagan MD DDS PhD

Hospital General Universitario de Valencia
Valencia, Spain

Dan Bagger-Sjöbäck MD PhD

Professor in Ear, Nose and Throat Diseases
Karolinska Institute
Stockholm, Sweden

David M Baguley BSc MSc MBA PhD

Consultant Audiological Scientist
Cambridge University Hospitals NHS Foundation Trust
Cambridge, UK

S Bahadur MS FAMS PhD

Professor of Otolaryngology and Head/Neck Surgery
All India Institute of Medical Sciences
New Delhi, India

Martin Bailey BSc FRCS

Consultant Paediatric Otolaryngologist
Great Ormond Street Hospital for Children
London, UK

John Bamford BA PhD

Ellis Llywd Jones Professor of Audiology and Deaf Education
School of Psychological Sciences
Faculty of Medical and Human Sciences
University of Manchester
Manchester, UK

Doris-Eva Bamiou MD MSc PhD

Consultant in Audiological Medicine
Department of Neuro-otology
National Hospital for Neurology and Neurosurgery; and
Honorary Senior Lecturer
Academic Unit of Audiological Medicine
University College London Institute of Child Health
Great Ormond Street Hospital
London, UK

Dev Banerjee BSc MBChB MD MRCP

Consultant Respiratory and Sleep Physician
Sleep and Ventilation Unit
Department of Respiratory Medicine
Birmingham Heartlands Hospital
Birmingham, UK

Graham Banfield MD DLO FRCS Ed (ORL-HNS)

Consultant ENT Surgeon
The Great Western Hospital
Swindon, UK

Jane A Baran PhD

Professor and Chair
Department of Communication Disorders
University of Massachusetts Amherst
Amherst, MA, USA

Michael E Baser†

Formerly of Department of Environmental Health Sciences
Johns Hopkins School of Hygiene and Public Health
Baltimore, MD, USA

Grant Bates BSc (Hons) BM Bch FRCS

Consultant ENT Surgeon
John Radcliffe Hospital
Oxford, UK

Nigel Beasley FRCS (ORL-HNS)

Consultant in Otolaryngology
Queen's Medical Centre
Nottingham, UK

Michael S Benninger MD

Chairman Department of Otolaryngology-Head and Neck Surgery
Henry Ford Hospital
Detroit, USA

Barry KB Berkovitz MSc PhD BDS FDSRCS (Eng)

Department of Anatomy and Human Sciences
School of Biomedical and Health Sciences
King's College
London, UK

Thanos Bibas MSc (Lond) DrMed FRCSI (Otol)

Consultant and Lecturer in Otolaryngology
Hippokrateion Hospital University of Athens
Athens, Greece

Carsten Bindslev-Jensen MD PhD DSc

Head, Allergy Center
Department of Dermatology
Odense University Hospital
Odense, Denmark

Brian JG Bingham MBChB FRCS Ed Glas

Consultant ENT Surgeon
Department of Otolaryngology
Victoria Infirmary; and
Honorary Senior Lecturer in Otorhinolaryngology
University of Glasgow
Glasgow, UK

† Deceased

Martin A Birchall MD (Cantab) FRCS FRCS (Oto) FRCS (ORL)

Professor of Laryngology
University of Bristol
Bristol, UK; and
Consultant in Otolaryngology Head and Neck Surgery
Royal United Hospital Bath NHS Trust
Bath, UK

Ian D Bottrill BM FRCS (ORL)

Consultant Otolaryngologist; and
Honorary Senior Lecturer
ENT Department
University of Oxford
John Radcliffe Hospital
Oxford, UK

An Boudewyns MD PhD

Professor of Otorhinolaryngology
Department of Otorhinolaryngology, Head and Neck Surgery
University of Antwerp Hospital – University of Antwerp
Antwerp, Belgium

Brett E Bouma PhD

Associate Professor, Department of Dermatology
Member of the Faculty of the Harvard-MIT Division of Health
Science and Technology
Harvard Medical School
Boston, MA, USA

Jean Bousquet MD

Service des Maladies Respiratoires
Hôpital Arnaud de Villeneuve
Montpellier, France

Patrick J Bradley MBA FRCS FRACS (Hon) FRCSLT (Hon)

Professor of Head and Neck Oncologic Surgery
Department of ORL-HNS
Nottingham University Hospitals
Queen's Medical Centre Campus
Nottingham, UK

Stefan Brew MB ChB MHB (Hons) MSc FRANZCR

Consultant Neuroradiologist
The National Hospital for Neurology and Neurosurgery
London, UK

Steven M Bromley MD

Clinical Assistant Professor of Neurology (Medicine)
and Attending Neurologist
University of Medicine and Dentistry of New Jersey
Robert Wood Johnson Medical School
Cooper University Hospital, Camden, NJ; and
Bromley Neurology PC, Audubon, NJ; and
Smell and Taste Center
University of Pennsylvania Medical Center
Philadelphia, PA
USA

Adolfo M Bronstein MD PhD FRCP

Professor of Clinical Neuro-otology; and
Head, Neuro-otology Unit
Division of Neuroscience and Mental Health
Charing Cross Hospital, Imperial College London; and
Honorary Consultant Neurologist
Charing Cross Hospital; and
National Hospital for Neurology and Neurosurgery
Queen Square, London, UK

Gerald Brookes FRCS

Consultant Otologist and Neuro-Otologist
The National Hospital for Neurology and Neurosurgery; and
The Royal National Throat, Nose and Ear Hospital
London, UK

George G Browning MD FRCS

Professor of Otorhinolaryngology
MRC Institute of Hearing Research
Glasgow Royal Infirmary
Glasgow, UK

Peter D Bull MB FRCS

Consultant Otolaryngologist
Royal Hallamshire Hospital and Sheffield Children's Hospital; and
Honorary Senior Clinical Lecturer
University of Sheffield
Sheffield, UK

Martin J Burton MA DM FRCS

Senior Clinical Lecturer
University of Oxford; and
Consultant Otolaryngologist
Oxford Radcliffe NHS Trust
Oxford, UK

James V Byrne MD FRCS FRCR

Professor of Neuroradiology
University of Oxford; and
Consultant Neuroradiologist
John Radcliffe Hospital
Oxford, UK

Melissa Calvin MRCOG PhD BSc (Hons)

Department of Obstetrics and Gynaecology
Lister Hospital
Stevenage, UK

Richard Canter PhD FRCS FRCS (Otol) Hon FRCS (Edin)

Consultant Otolaryngologist
Royal United Hospital; and
Honorary Senior Lecturer
University of Bath
Bath, UK

Paul Carding FRCSLT

Professor of Voice Pathology
The Medical School, Newcastle University; and
Head of Speech, Voice and Swallowing Department
Otolaryngology Directorate, Freeman Hospital
Newcastle on Tyne, UK

A Simon Carney BSc (Hons) MBChB FRCS FRACS MD
Associate Professor and Head of ENT Unit
Flinders University and Flinders Medical Centre
Adelaide, South Australia

Anna Cassoni BSc FRCP FRCR
Consultant in Clinical Oncology
University College Hospitals NHS Foundation Trust
London, UK

Helen Caulfield MBBS FRCS (ORL-HNS)
Consultant ENT Surgeon
Department of Otolaryngology
The Royal Free Hospital
London, UK

Roderick Cawson† MD FRCPPath
Formerly Emeritus Professor of Oral Medicine
Guy's Hospital
London, UK

Borka Ceranic MD ENTspec PhD
Consultant in Audiological Medicine
Department of Audiology
St George's Hospital
London, UK

Swarupsinh V Chavda MBChB DMRD FRCR
Consultant Neuroradiologist and Honorary Senior Lecturer
Queen Elizabeth Hospital
University Hospital Birmingham Foundation Trust
Birmingham, UK

Elfy B Chevretton BSc MBBS FRCS MS
Consultant Otolaryngologist
Department of ENT Surgery
Guy's and St Thomas' NHS Trust
London, UK

Peter Clarke BSc FRCS
Consultant ENT Surgeon
Charing Cross Hospital
London, UK

Ray Clarke BSc DCH FRCS FRCS (ORL)
Consultant Paediatric Otolaryngologist
Royal Liverpool University Children's Hospital
Alder Hey, Liverpool, UK

Susan Clarke MSc FRCP FRCR
Senior Lecturer and Consultant Physician
Department of Nuclear Medicine
Guy's and St Thomas' Hospital
London, UK

Rogan Corbridge MBBS BSc FRCS FRCS (ORL)
Consultant ENT Surgeon
Oxford Centre for Head and Neck Oncology
John Radcliffe Hospital
Oxford, UK

Robin T Cotton MD
Director, Pediatric Otolaryngology–Head and Neck Surgery
Children's Hospital Medical Center; and
Professor of Pediatric Otolaryngology
Department of Otolaryngology, Head and Neck Surgery
University of Cincinnati College of Medicine
Cincinnati, OH, USA

Graham J Cox BDS FRCS
Consultant ENT Surgeon; and
Macmillan Head and Neck Surgical Oncologist
John Radcliffe Hospital
Oxford, UK

Alistair Cranston MBBS FRCA
Consultant Anaesthetist
Birmingham Children's Hospital
Birmingham, UK

Cor WRJ Cremers
Department of Otorhinolaryngology
University Medical Center
St Radboud
Nijmegen, The Netherlands

Ian S Curthoys PhD
Emeritus Professor
School of Psychology
University of Sydney
Sydney, Australia

Rosalyn A Davies FRCP PhD
Consultant in Audiovestibular Medicine
Department of Neuro-Otology
The National Hospital for Neurology and Neurosurgery; and
Honorary Senior Lecturer
Institute of Neurology
Queen Square, London, UK

Martin Dawes MB BS MD (Lond) FRCGP
Chair, Family Medicine
McGill University
Quebec, Canada

Ranit De MPhil FRCS (ORL-HNS)
Consultant ENT Surgeon
University Hospital North Staffordshire NHS Trust; and
Stoke-on-Trent and Mid-Staffordshire NHS Trust
Stafford, UK

Sujata De MBBS FRCS (ORL-HNS)
Consultant Paediatric Otorhinolaryngologist
Alder Hey Children's Hospital
Liverpool, UK

Charles Diamond FRCS (Glas) Dip Pall Med
Honorary Consultant Otolaryngologist
Freeman Hospital and St. Oswald's Hospice
Newcastle upon Tyne, UK

Oscar Dias MD PhD
Associate Professor
Department of Otolaryngology, Voice and Communication Disorders
Faculty of Medicine of Lisbon
Lisbon, Portugal

Harvey Dillon B Eng (Hons I) PhD
Director of Research
National Acoustic Laboratories
Chatswood, Australia

Richard L Doty PhD
Smell and Taste Center
University of Pennsylvania Medical Center
Philadelphia, PA, USA

M Stephen Dover FDSRCS FRCS
Consultant Oral and Maxillofacial Surgeon, and
Honorary Senior Lecturer
Department of Maxillofacial Surgery
University Hospital Birmingham NHS Foundation Trust
Birmingham, UK

Wolfgang Draf Prof Dr Med Dr HC FRCS
Director, Department of Ear, Nose and
Throat Diseases, Head and Neck Surgery
International Neuroscience Institute
Hanover, Germany

Adrian Drake-Lee MMed PhD FRCS
Consultant ENT Surgeon
Queen Elizabeth Hospital
University Hospital, NHS Trust
Birmingham, UK

Elizabeth Drewe MBBS PhD MRCP MRCPath
Consultant Clinical Immunologist
Nottingham University Hospitals NHS Trust
Nottingham, UK

Stephen R Durham MA MD FRCP
Professor of Allergy and Respiratory Medicine
Imperial College School of Medicine
National Heart and Lung Institute
London, UK

Sunil Narayan Dutt MS DNB PhD FRCS Ed (ORL-HNS) DLO (Eng) DORL
Senior Consultant and Clinical Coordinator
Department of Otolaryngology and Head and Neck Surgery
Apollo Group of Hospitals
Bangalore, India

Charles East FRCS
Consultant Otolaryngologist, Head and Neck Surgeon
The Royal Free Hampstead NHS Trust
London, UK

Ronald Eccles BSc PhD DSc
Director, Common Cold Centre and
Healthcare Clinical Trials
Cardiff School of Biosciences
Cardiff University
Cardiff, Wales, UK

D Gareth R Evans MD FRCP
Professor, Department of Medical Genetics
St Mary's Hospital
Manchester, UK

Matthew Evans PhD
Editorial Manager
Caudex Medical
Oxford, UK

Johannes J Fagan MBChB, FCS (SA) MMed (Otol)
Professor and Chairman
Division of Otolaryngology
University of Cape Town and Groote Schuur Hospital
Cape Town, South Africa

Andrew D Farmery BSc MA MD FRCA
Senior Lecturer in Anaesthetics
Nuffield Department of Anaesthetics
University of Oxford
Oxford, UK

Neil Fergie FRCS MD
Consultant in Otorhinolaryngology Head and Neck Surgery
Kings Mill Hospital, Mansfield; and
Queens Medical Centre
Nottingham, UK

John Fleetham MB BS FRCP(C)
Professor of Medicine
Respiratory Division
University of British Columbia and Vancouver Hospital
Vancouver, BC, Canada

Bill Fleming FRACS FRCS
Consultant Endocrine Surgeon
Hammersmith Hospital
Imperial Healthcare NHS Trust
London, UK

Liam M Flood MB BS FRCS

ENT Consultant

James Cook University Hospital

Middlesbrough, UK

Adrian Fourcin PhD FLoA

Emeritus Professor, Department of Phonetics and Linguistics

University College London

London, UK

Haematology SpR
Hammersmith Hospitals NHS Trust
London, UK

Stephen R Young BSc (Hons) PhD

Faculty of Science
The American International University in London
Surrey, UK

Preface

Fifty-five years have passed since the first edition of *Scott-Brown's Otorhinolaryngology: Head and Neck Surgery* was published. Many otorhinolaryngologists have read at least one edition, committed it to memory and passed their specialist examinations because of it. All will have kept referring to it throughout their careers and remember it with affection. Looking back it is apparent that a radical change in structure and format has taken place every 15 to 20 years. It is 20 years since Alan Kerr made the last radical change with the publication of the 5th edition, 20 years that have seen an information technology explosion. The internet, on-line libraries, e-delivery of journals and increasingly books, computerised search engines, CD-ROMs, DVDs, digital photography; the list goes on. These technological advances have transformed medical education, influenced significantly the way the current generation learns and the methods by which their competencies and knowledge are assessed. Certainly sufficient time has elapsed for *Scott-Brown* to evolve dramatically once more. This edition has been completely re-written. It bears little resemblance to its predecessors other than by title, and in its philosophy to provide a complete resume of the knowledge base that underpins modern ORL practice and which will guide clinicians in their everyday patient care for years to come. The number of chapters has almost doubled, with large topics dissected into more digestible parts. This reflects the expansion of our specialty such that it is now a group of subspecialties linked by the common thread, each concerned with, and committed to, the care of patients with disorders of the head and neck.

Our authors are the leading experts in their respective fields of interest and have been selected from all over the world. Almost all the text is illustrated in colour and it comes with its own CD-ROM, containing all the text and illustrations in an accessible and searchable form, with references linked to PubMed.

So what else could the trainee or practising otorhinolaryngologist want from the definitive reference to the field at the beginning of the new millennium? Quite simply, the level of evidence for the advice we offer and the practice we undertake. Nowadays specialties need to define best clinical practice, if only to guide and remind health care providers of their duty to their patients to practice in accordance with accepted evidence and to

strive for excellence in clinical standards at all times. Surgeons also need to know how their actions might be viewed by the courts and the areas of practice that are currently exercising the legal profession. This edition has tried to provide that information.

It has not been an easy task for our contributors, some of whom were not writing in their mother tongue. That they were able to write to a structured format was much to their credit. I was fortunate to recruit, and am extremely grateful to, my team of section editors all of whom worked tirelessly with a common purpose. George G Browning, Martin J Burton, Ray Clarke, John Hibbert, Nicholas S Jones, Valerie J Lund, Linda M Luxon and John C Watkinson represent some of the very best and most respected clinicians in the United Kingdom, each one an international authority, each one with a heavy professional commitment. Alan Kerr's advice and encouragement throughout was always welcome and extremely useful. Marcelle McNamara came to my aid and assistance numerous times during the project. She gave tirelessly of her time and energy during a very serious illness, writing chapters and putting others into format and a more readable form. She was an example and inspiration throughout.

The creation of this edition has also been an interesting experience for the publishing staff. During a lengthy period of gestation, this text has changed ownership several times as the publishing houses traded and realigned their lists. Without the drive and perseverance of Zelah Pengilly and Jo Koster from Hodder Education it would surely have fallen by the wayside. Words cannot express my gratitude to them adequately. Understanding when clinical work overwhelmed me, they hid their frustrations over slow progress or irritatingly incomplete manuscripts. They buoyed us all up when the end seemed so far away.

Sadly, some of our contributors will never see their chapters in print as they have died during the preparation of this text. Some had long, unpleasant illnesses but wrote despite them. Others were cut down unexpectedly in their prime but have now left a legacy, and a few were my close friends and colleagues. I am proud to have my name linked permanently through this publication with Michael Baser, Roderick Cawson, Susanna Leighton,

William Owen, Robert Sanderson and Antonio Vignola. We hope that their families will draw some comfort also by seeing their loved ones live on in this book.

Finally, there are four very special people whose constant love and affection drives me on through life. They are of course my wife, Ann, and our children,

Andrew, Clare and Mark. They too will breathe a deep sigh of relief with the publication of this text and I thank them with all my heart.

Michael Gleeson
September 2007

How to use this book

This new edition of *Scott-Brown's Otorhinolaryngology, Head and Neck Surgery* incorporates some special features to aid the readers' understanding and navigation of the text. These are described below.

SEARCH STRATEGY

The majority of the chapters feature a search strategy indicating the key words used by the author when conducting their literature review in order to prepare the chapter, so that the reader can repeat and develop the search.

EVIDENCE SCORING

For the major sections in each chapter, the authors have used a hierarchical system to indicate the level of evidence supporting their statements. This is shown in the text in the form [***], with the number of stars indicating the level of evidence. The key to this system is shown in the table below.

Level	Category of evidence
****	Systematic reviews, meta-analyses of randomized controlled trials and randomized controlled trials
***	Non-randomised studies
**	Observational or non-experimental studies
*	Expert opinion

Where no level is shown, the quality of supporting evidence, if any exists, is of low grade only (for example, case reports, clinical experience etc.). For more information on evidence scoring, please refer to Chapter 304, Evidence-based medicine; and 305 Critical appraisal skills.

CLINICAL RECOMMENDATIONS

The authors have indicated the basis on which they have made clinical recommendations by grading them according to the level of the supporting evidence. This is shown in the text in the form [Grade A], with the grade indicating the level of evidence supporting the recommendation. The key to this system is shown in the table below.

Grade	Nature of supporting evidence
A	Recommendation based on evidence from meta-analyses of randomized controlled trails
B	Recommendation based on evidence from high quality case-controlled or cohort studies
C	Recommendation based on evidence from low quality case-controlled or cohort studies
D	Recommendation based on evidence from clinical series or expert opinion

Recommendations are graded where the author is satisfied that the literature supports such a grading; otherwise a grading may not be given.

REFERENCE ANNOTATION

The reference lists are annotated with an asterisk, where appropriate, to guide readers to key primary papers and major review articles. We hope that this feature will render the lists of references more useful to the reader and will encourage self-directed learning among both trainees and practicing physicians.

Abbreviations

2,3DPG	2,3-diphosphoglycerate	Ad-VEGF	adenovirus-encoding vascular endothelial growth factor
2D	two-dimensional	AECRS	acute exacerbation of chronic rhinosinusitis
3,4-DAP	3,4-diaminopyridine	AED	aerodynamic equivalent diameter
3D	three-dimensional	AEDS	atopic eczema dermatitis syndrome
5-FdUMP	5-fluoro-2 deoxyuridine monophosphate	AEF	auditory-evoked cortical magnetic field
5-FU	5-fluorouracil	AF	atrial fibrillation; or anterior fontanelle
5-FUMP	5-fluorouridine monophosphate	AFB	acid-fast bacilli
5-HT	5-hydroxytryptamine	AFRS	allergic fungal rhinosinusitis
6MP	6-Mercaptopurine	AgNOR	silver staining nucleolar organizer region
18-FDG	2-18-fluoro-2-deoxy-D-glucose	AHA	American Heart Association
A	adenine; or anterior	AHCPR	Agency for Health Care Policy and Research (USA)
AABR	automated auditory brainstem response	AHI	apnoea/hypopnoea index
AAHL	age-associated hearing loss	AI	apoptotic index
AAOHNS	American Academy of Otolaryngologists/Head and Neck Surgeons	AICA	anterior inferior cerebellar artery
AAV	adeno-associated virus	AIDS	acquired immunodeficiency syndrome
ABC	aspiration biopsy cytology	AIRE	autoimmune regulator gene
ABEP	auditory nerve and brainstem evoked potential	AJCC	American Joint Committee on Cancer
ABG	air-bone gap	ALD	assistive listening device
ABI	auditory brainstem implant	ALEP	auditory long-latency (or late) evoked potential
ABLB	alternate binaural loudness balance	ALL	acute lymphoblastic leukaemia
ABPA	allergic bronchopulmonary aspergillosis	$\alpha 2\beta 2$	two α and two β globin chains
ABR	auditory brainstem response; or acoustic brainstem evoked response	$\alpha 2\delta 2$	HbA2
ABRS	acute bacterial rhinosinusitis	$\alpha 2\gamma 2$	foetal haemoglobin
AC	air conduction; or alternating coupled	ALPS	autoimmune lymphoproliferative syndrome
ACC	adenoid cystic carcinoma; or American College of Cardiology	ALS	amyotrophic lateral sclerosis
ACE	angiotensin-converting enzyme	ALT	alternative lengthening of telomere; or alternating chemoradiotherapy
ACF	anterior cranial fossa	ALTB	acute laryngotracheobronchitis
ACh	Acetylcholine	ALTE	apparent life-threatening event
AChR	acetyl choline receptor	AML	acute myeloid leukaemia
ACT	Aid for Children with Tracheostomies	AN	acoustic neuroma; or auditory neuropathy; or audiovestibular nerve
ACTH	adrenocorticotrophic hormone	ANA	anti-nuclear antibody
A/D	analogue-to-digital	AN/AD	auditory neuropathy/auditory dyssynchrony
AD	Alzheimer's disease	ANCA	antineutrophil cytoplasmic antibody
ADA	adenosine deaminase	AND	allow a natural death
ADAM-33	A disintegrin and metalloprotease 33k	ANUG	acute necrotizing ulcerative gingivitis
ADCC	antibody-dependent cellular cytotoxicity	AOAE	automated otoacoustic emission
ADH	antidiuretic hormone	AoCD	anaemia of chronic disease
ADHD	attention deficit hyperactivity disorder	AOM	acute otitis media
ADR	adverse drug reaction		

AON	anterior olfactory nucleus	BAHNO	British Association of Head and Neck Oncologists
AP	anterior–posterior; or action potential	BAO-HNS	British Association of Otorhinolaryngologists – Head and Neck Surgeons
APB	ALT-associated promyelocytic leukaemia body	BAPO	British Association for Paediatric Otolaryngology
APC	antigen presenting cell; or activated protein C; or argon plasma coagulation; or adenomatous polyposis coli	BCC	basal cell carcinoma
APD	auditory processing disorder	BCG	Bacillus Calmette–Guérin
APECED	autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy	BCHA	bone conductor hearing aid
APHAB	Abbreviated Profile of Hearing Aid Benefit	BCSH	British Committee for Standards in Haematology
APL	anti-phospholipid	BDP	beclomethasone dipropionate
APMET	aggressive papillary middle ear tumour	BE	bulla ethmoidalis
APQ	amplitude perturbation quotient	BF	biofeedback
APTT	activated partial thromboplastin time	BFU-E	burst-forming unit erythroid
APUD	amine precursor uptake and decarboxylation	BiPAP	bilevel positive airway pressure
ARF	acute renal failure	BIPP	bismuth and iodoform paraffin paste
ARIA	allergic rhinitis and its impact on asthma	BL	Burkitt's lymphoma
ARR	absolute risk reduction	BMA	British Medical Association
ARS	acute rhinosinusitis	BMI	body mass index
ART	advanced rotating tomograph; or antiretroviral therapy	BMP	bone morphogenetic protein; or bone morphogenic protein
ARTA	age-related typical audiogram	BMS	burning mouth syndrome
ASA	aspirin-induced asthma; or aspirin-sensitive asthma; or American Society of Anesthesiologists	BMT/SCT	bone marrow stem cell transplantation
a-SCC	anterior semicircular canal	BOA	behavioural observation audiometry
ASIC	application specific integrated circuit	BOLD	blood oxygenation level-dependent
ASL	American sign language; or arterial spin labelling	BOR	brachio-oto-renal
ASPO	American Society of Pediatric Otolaryngologists	BP	blood pressure
ASSR	auditory steady state response	BPD	bronchopulmonary dysplasia
AST	arterial spin tagging	BPPV	benign positional paroxysmal vertigo
AT	ataxia telangiectasia; or auditory therapy or training	BPV	benign paroxysmal vertigo; or benign positional vertigo
ATD	ascending tract of Deiters	BS	Behçet's syndrome
ATIII	antithrombin III	BSE	bedside swallowing examination; or bovine spongiform encephalopathy
ATN	auriculotemporal nerve	BSL	British sign language
ATP	adenosine triphosphate	BTE	behind the ear
ATRA	all-trans retinoic acid	BVF	bilateral vestibular failure
AUC	area under the curve	C	cytosine
AV	apical vesicles; or arteriovenous	CAD	caspase-activated DNase
AVCN	anteroventral cochlear nuclei	CADCAM	computer-aided design, computer-aided manufacture
AVM	arteriovenous malformation	CAGE	cerebral air gas embolism
aVOR	angular VOR	cAMP	3',5'-monophosphate
AZT	3'azido3'deoxythymidine zidovudine; or azothiaprime	CANS	central auditory nervous system
		CAP	compound action potential; or category of auditory performance
		CAPD	central auditory processing disorder
BAC	bacterial artificial chromosome	CaR	calcium sensing receptor
BACDA	British Association of Community Doctors in Audiology	CAS	computer-assisted surgery
BADS	British Association of Day Surgery	CATCH-22	cardiac defects, abnormal facies, thymic hypoplasia, cleft palate and hypocalcaemia-22
BAES	British Association of Endocrine Surgeons	CB	concha bullosa; or critical bandwidth
BAHA	bone-anchored hearing aid	CBF	ciliary beat frequency

CBT	cognitive-behavioural therapy	CNO	chronic nasal obstruction
CCA	common carotid artery	CNS	central nervous system
CCDU	colour-coded duplex ultrasonography	CO ₂	carbon dioxide
CCR	chemokine receptor	COAD	chronic obstructive airway disease
CCW	counter-clockwise	COM	chronic otitis media
CD	cluster of differentiation; or colloid droplets; or compact disk	COPD	chronic obstructive pulmonary disease
CDA	cold dry air	COR	conditioned orientation reflex
CDC	Centers for Disease Control and Prevention	COSI	Client Oriented Scale of Improvement
CDK	cyclin-dependent kinase	COX-2	cyclo-oxygenase 2
CDP	computerized dynamic posturography	CP	cleft palate
CE-CT	contrast-enhanced computed tomography	CPA	cerebellopontine angle
CEA	carcinoembryonic antigen	CPAP	continuous positive airway pressure
CEPOD	Confidential Enquiry into Perioperative Deaths	CPD	citrate phosphate dextrose; or continuing professional development
CER	control event rate	CPG	central pattern generator
CERA	cortical evoked response audiometry	CPO	cleft palate only
CEVMP	click-evoked vestibular myogenic potential	CPPIH	Commission for Patient and Public Involvement in Health (UK)
CF	cystic fibrosis; or characteristic frequency	CPR	cardiopulmonary resuscitation
CFD	colour-flow duplex Doppler	CQI	continuous quality improvement
CFR	craniofacial resection	CREST	calcinosis, Raynaud's, oesophageal involvement, sclerodactyly, telangiectasis
CFTR	cystic fibrosis transmembrane conductance regulator	CRF	corticotrophin-releasing factor
CFU	colony-forming unit	CRH	corticotropin-releasing hormone
CFU-GM	colony-forming unit, granulocyte- macrophage	CROS	contralateral routing of signal or sound
CFU-Mk	colony-forming unit, megakaryocyte	CRP	C-reactive protein; or canalith repositioning procedure
CG	clinical governance	CRRT	continuous renal replacement therapy
CGD	chronic granulomatous disease	CRS	chronic rhinosinusitis; or congenital rubella syndrome
CGH	comparative genomic hybridization	CRSS	chronic rhinosinusitis
CGRP	calcitonin gene-related peptide	CS	corticosteroid
CGST	Clinical Governance Support Team	CSCI	Commission for Social Care Inspection (UK)
CHARGE	coloboma, heart defects, atresia choanae, retardation of growth, genital anomalies and ear abnormalities	CSF	cerebrospinal fluid
CHART	continuous, hyperfractionated, accelerated radiotherapy	CSM	Committee on Safety of Medicines
CHI	Commission for Healthcare Improvement (UK)	CSOM	chronic suppurative otitis media
CI	cochlear implant; or cardiac index; or confidence interval; or concha inferior	CT	computed tomography
CID	Central Institute for the Deaf	CTA	composite tissue allograft
CJD	Creutzfeldt-Jakob disease	CTL	cytotoxic T-lymphocyte
CL	cleft lip	CTLA	cytotoxic T-lymphocyte-associated antigen
CL/P	cleft lip with or without cleft palate	CTLL	cytotoxic T-lymphocyte leukaemic
CLL	chronic lymphatic leukaemia; or chronic lymphocytic leukaemia	CTM	cricothyroid membrane
CM	concha media; or cochlear microphonic; or cricothyroid muscle	cTNM	clinical tumour, nodes, metastases
CMAP	compound muscle action potential	CTR	cricotracheal resection
CME	continuing medical education	CTZ	chemoreceptor trigger zone
CMI	cell-mediated immunity	Cu-ATSM	Cu(II)-diacetyl-bis-N4- methylthiosemicarbozone
CML	chronic myeloid leukaemia	CUP	carcinoma of unknown primary origin
CMT	Charcot-Marie-Tooth	CUSA	cavitational ultrasonic surgical aspirator
CMV	<i>Cytomegalovirus</i>	CVA	cerebrovascular accident
CN	cranial nerve; or cochlear nuclei; or cochlear nerve	CVD	central vestibular disorder
		CVI	common variable immunodeficiency
		CVP	central venous pressure
		CW	clockwise
		CXR	chest x-ray
		CYP	cytochrome P450

DACH	diaminocyclohexane	EAC	external auditory canal; or external acoustic canal
DAHANCA	Danish Head and Neck Cancer Study	EAL	ethmoidal artery ligation
DAHNO	Data for Head and Neck Oncology (UK)	EAM	external auditory meatus
dB	decibel	EB	epidermolysis bullosa
dB SPL	decibel sound pressure level	EBM	evidence-based medicine
DBPCFC	double-blind placebo-controlled food challenge	EBNA	Epstein–Barr virus-associated nuclear antigen
DCIA	deep circumflex iliac artery	EBP	evidence-based practice
DCN	dorsal cochlear nucleus	EBV	Epstein–Barr virus
DCR	dacryocystorhinostomy	EC	embryonic carcinoma
DD	death domain	ECA	external carotid artery
DDHS	Direct Drive Hearing System	ECAL	external carotid artery ligation
DFF	DNA fragmentation factor	ECAP	electrically evoked compound action potential
DFN3	deafness type 3	ECC	extracorporeal circuit
DFO-H	deferrioxamine-hesperan	ECG	electrocardiogram
DHA-S	dehydroepiandrosterone sulphate	ECM	extracellular matrix
DHE	dihaematoporphyrinether	ECMO	extracorporeal membrane oxygenation
DHI	dizziness handicap inventory	EcochG	electrocochleography
DHTR	delayed haemolytic transfusion reaction	ECog	electrocochleogram
DIC	disseminated intravascular coagulation	ECOG	Eastern Cooperative Oncology Group (USA)
DIEP	deep inferior epigastric perforator	ECP	eosinophil cationic protein
DILS	diffuse infiltrated lymphocytosis syndrome	ECR	extracapsular rupture
DIT	diiodotyrosine	EDGT	early goal-directed therapy
DLE	discoid lupus erythematosus	EDN	eosinophil-derived neurotoxin
DM	diabetes mellitus	EDS	excessive daytime sleepiness
DMD	Duchenne muscular dystrophy	EDTA	ethylenediaminetetraacetic acid
DMSA	dimercapto succinic acid	EDV	end diastolic velocity
DMSO	dimethylsulfoxide	EE	external frontoethmoidectomy
DNA	deoxyribonucleic acid	EEG	electroencephalography; or electroencephalogram
DNAR	do not attempt resuscitation	EER	experimental event rate
DNL	nasolacrimal duct	EFS	event-free survival
DNR	do not resuscitate	EG	embryonic germ
dNTP	deoxynucleoside triphosphate	EGF	epidermal growth factor
DP	directional preponderance	EGFR	epidermal growth factor receptor
DPA	Data Protection Act (UK)	EIA	enzyme immunoassay
DPOAE	distortion product otoacoustic emission	ELDCR	endonasal laser dacryocystorhinostomy
DR	death receptor; or drug resistance	ELG	electrolaryngography
DRS	Dysphagia Research Society	ELISA	enzyme-linked immunosorbent assay
DSA	digital subtraction angiography	ELST	endolymphatic sac tumour
DSI	Dysphonia Symptom Index	EM	erythema multiforme
DSL	desired sensation level	EMEA	European Agency for the Evaluation of Medicinal Products
DTD	DT-diaphorase	EMG	electromyography
DTIC	dimethyl triazeno imidazole carboxamide	EMI	elective mucosal irradiation
dTMP	deoxythymidine monophosphate	EN	enteral nutrition
DTPA	diethylene triamine pentacetic acid	ENA	extra nuclear antigen
dUMP	deoxyuridine monophosphate	ENG	electronystagmography
DVB	degree of voice break	ENoG	electroneurography
DVLA	Driver and Vehicle Licensing Authority (UK)	ENT	ear, nose and throat
DVN	descending vestibular nuclei	EOG	electroolfactogram; or electrooculography
DVT	deep vein thrombosis	EORTC	European Organisation for Research and Treatment of Cancer
DWI	diffusion weighted image	EP	endolymphatic potential
EA	episodic ataxia; or early antigen		
EAACI	European Academy of Allergology and Clinical Immunology		

EPO	erythropoietin	FN	facial nerve
EQ-5D	EuroQol	FNA	fine-needle aspiration
ER	enhancement ratio; or endoplasmic reticulum	FNAB	fine-needle aspiration biopsy
ERB	equivalent rectangular bandwidth	FNAC	fine-needle aspiration cytology
ERM	ezrin, radixin, moesin	FOAR	fronto-orbital advancement and remodelling
ERP	event-related potential	FOI	fibreoptic orotracheal intubation
ERT	external radiotherapy	FPANS	fluticasone propionate aqueous nasal spray
Er:YAG	erbium:yttrium-aluminium-garnet	FS	folliculostellate
ES	embryonic stem; or endolymphatic sac	FSH	follicle-stimulating hormone
ESPAL	endonasal ligation of the sphenopalatine artery	FT	fibrous tissue
ESR	erythrocyte sedimentation rate	FTA	fluorescent treponemal antibody
ESS	endoscopic sinus surgery; or Epworth Sleepiness Scale	FTA-ABS	fluorescent treponemal antibody test
ET	essential thrombocytosis; or endotracheal tube	FTC	frequency threshold curve
ET-1	endothelin-1	FTP	Fitness to Practise
ETT	endotracheal tube	G	guanine
EU	European Union	G6PD	glucose-6-phosphate deficiency
EUA	examination under anaesthesia	Ga-67	gallium
EVAS	enlarged vestibular aqueduct syndrome	GABA	gamma-aminobutyric acid
EXIT	extrauterine intrapartum treatment	GABHS	group A beta-haemolytic streptococcus
F ₀	fundamental frequency	GAG	glycosaminoglycan
FAAF	four alternative auditory feature	GALT	gut-associated lymphoid tissue
Fab	fragment antigen binding	GAS	Goal Attainment Scaling
FACS	fluorescence-activated cell sorter	G&S	group and screen
FACT	functional assessment of cancer therapy	GBI	Glasgow Benefit Inventory
FAMM	facial artery myomucosal flap	GBLC	geometric broken line closure
Fas-L	Fas ligand	GCS	Glasgow Coma Score
FBC	full blood count	G-CSF	granulocyte-colony stimulating factor
Fc	fragment crystallizable	GD	Graves' disease
FD	fibrous dysplasia	GERD	gastrooesophageal reflux disease
FDA	Food and Drug Administration (USA)	GH	growth hormone
FDG	fluorodeoxyglucose; or 2-[¹⁸ F] fluoro-2-deoxy-D-glucose; or F18-fluoro-2-deoxy-D-glucose	GHABP	Glasgow Hearing Aid Benefit Profile
FDG-PET	2-[¹⁸ F] fluoro-2-deoxy-D-glucose-positron emission tomography; or fluorine-18-labelled deoxyglucose positron emission tomography	GHRH	growth hormone-releasing hormone
FEES	fibreoptic endoscopic evaluation of swallowing	GI	gastrointestinal
FEESST	fibreoptic endoscopic evaluation of swallowing with sensory testing	GIA	gravitoinertial acceleration
FESS	functional endoscopic sinus surgery	GIC	glass ionomer cement
FETNIM	fluorine-18 fluoroerythronitroimidazole	GIST	gastrointestinal stromal tumour
FFP	fresh frozen plasma	GLM	ground lamella of middle turbinate, middle (frontal) portion
FFT	fast Fourier transform	GMC	ganglion mother cell; or General Medical Council (UK)
FGF	fibroblast growth factor	GM-CSF	granulocyte-macrophage colony-stimulating factor
FHH	familial hypocalciuric hypercalcaemia	GN	glossopharyngeal nerve
FISH	fluorescence <i>in situ</i> hybridization	GNE	glottal-to-noise excitation
FIV	feline immunodeficiency virus	GnRH	gonadotropin-releasing hormone
FLAIR	fluid attenuated inversion recovery	GOR	gastro-oesophageal reflux
FMISO	fluorine-18 fluoromisonidazole	GORD	gastro-oesophageal reflux disease
fMRI	functional magnetic resonance imaging	GOSH	Great Ormond Street Hospital (UK)
		gp	glycoprotein
		GP	general practitioner
		GPN	glossopharyngeal neuralgia
		GPP	gingivo-periosteoplasty
		G protein	guanine nucleotide-binding regulatory protein
		GPB2	growth factor receptor binding protein 2

GSH	glutathione	HMWC	high molecular weight compound
GSPN	greater superficial petrosal nerve	HNC	head and neck cancer
GST	glutathione S-transferase	HNR	harmonics-to-noise ratio
GSW	gun shot wound	HNRQ	Head and Neck Radiotherapy Questionnaire
GTN	nitroglycerin	HNSCC	head and neck squamous cell carcinoma
GTR	guided tissue regeneration	HPA	hypothalamic–pituitary–adrenal
GVHD	graft-versus-host disease	HPC	haemangiopericytoma
		HPD	haematoporphyrin derivative
H&E	haematoxylin and eosin	HPL	horizontal partial laryngectomy
H&N	head and neck	HPT	hyperparathyroidism
H2	histamine receptor type 2	HPV	human papillomavirus; or human herpes virus 8
HA	hydroxyapatite		
HAART	highly active antiretroviral therapy	HRA	Human Rights Act
HAE	hereditary angioedema	HRCT	high-resolution computed tomography
HAEM	HSV-associated erythema multiforme	HRM	high-resolution manometry
HAPI	Hearing Aid Performance Inventory	HRQOL	health-related quality of life
HB	House–Brackmann	HRT	hormone replacement therapy
Hb	haemoglobin	HS	hiatus semilunaris
HbA	adult haemoglobin	h-SCC	horizontal semicircular canal
HBO	hyperbaric oxygen	HSCT	haemopoietic stem cell transplant
HBOT	hyperbaric oxygen therapy	HSMN	hereditary sensory-motor neuropathy
HBsAg	hepatitis B surface antigen	HSPG	heparin sulphate proteoglycan
HC	Healthcare Commission (UK)	HSV	herpes simplex virus
HCA	hydroxycarbonate apatite	HSV-1	herpes simplex virus type 1
HCG	human chorionic gonadotrophin	HSV-2	herpes simplex virus type 2
HCSU	Health Care Standards Unit (UK)	HSV-TK	herpes simplex thymidine kinase
Hct	haematocrit	HT	hydroxytryptamine
HCV	hepatitis C virus; or human T-lymphocytic virus 1	hTERT	human telomerase reverse transcriptase
		hTR	human telomerase RNA
HD	haemodialysis	HU	Hounsfield unit
HDL	high-density lipoprotein	HUI	Health Utilities Index
HDM	house dust mite	HUS	haemolytic uraemic syndrome
HDPE	high-density polyethylene	Hz	hertz
HDU	high dependency unit	HZV	herpes zoster virus
He-Ne	helium-neon		
HEp-2	human epithelial type 2	IAC	internal auditory canal
HFT	hereditary familial telangiectasia	IAM	internal auditory meatus
HGF	hepatocyte growth factor	IBP	invasive monitoring of blood pressure
HHI	Hearing Handicap Inventory	IC	inferior colliculus; or immunochemistry
HHIE	Hearing Handicap Inventory for the Elderly	ICA	internal carotid artery
HHT	hereditary haemorrhagic telangiectasia	ICAM	intercellular adhesion molecule
HHV-6	human herpesvirus 6	ICAM-1	intercellular adhesion molecule 1
HHV-8	human herpesvirus 8	ICD	International Classification of Disease
HI	hearing impaired	ICM	intensive care medicine
HiB	<i>Haemophilus influenzae</i> B	ICP	intracranial pressure
HIT	heparin-induced thrombocytopenia	ICRA	International Collegium of Rehabilitative Audiology
HITT	heparin-induced thrombocytopenia with thrombosis	ICU	intensive care unit
		ID	inferior dental
HIV	human immunodeficiency virus	IDA	iron deficiency anaemia
HIV-SGD	HIV-associated salivary gland disease	IDT	infant distraction test
HJB	high jugular bulb	IDU	intravenous drug user
HL	hearing loss; or hearing level; or hairy leukoplakia	IF	intrinsic factor
HLA	human leukocyte antigen	IFN	interferon
HM	history of migraine; or hemifacial microsomia	IFN- α	interferon-alpha
		IFN- β	interferon-beta
HMW	high molecular weight	IFN- γ	interferon gamma

IFNP	idiopathic facial nerve paralysis	K	Kirschner
Ig	immunoglobulin	KAR	killer activating receptor
IgE	immunoglobulin E	keV	kilo electron volt
IGF	insulin-like growth factor	KIR	killer inhibitory receptor
IGFI	insulin-like growth factor I	KS	Kaposi's sarcoma
IGFII	insulin-like growth factor II	KSS	Kearns-Sayre syndrome
IgG	immunoglobulin G	KTP	potassium titanyl phosphate
IGS	image-guided surgery		
IHAFF	International Hearing Aid Fitting Forum	LA	lymphangioma
IHC	immunohistochemistry; or inner hair cell	LAD	leukocyte adhesion defect
		LAP	left anteroposterior
IHS	International Headache Society	LARP	left anterior-right posterior
IL	interleukin	LAUP	laser-assisted uvulopalatoplasty
IL-1	interleukin-1	LB	lateral bundle
IL-2	interleukin-2	LCH	Langerhans' cell histiocytosis
IL-3	interleukin-3	LCM	laser capture microdissection
IL-6	interleukin-6	LD	lymphocytic depleted
ILMA	intubating laryngeal mask airway	LDH	lactate dehydrogenase
IMA	internal maxillary artery	LDL	low-density lipoprotein; or loudness discomfort level
IMAL	internal maxillary artery ligation		
IMF	intermaxillary fixation	LDUH	low-dose unfractionated heparin
IMRT	intensity-modulated radiation therapy	LED	light-emitting diode
IMSPAC	imitative test of speech pattern contrast perception	LFA	lymphocyte-function associated antigen
		LGOB	loudness growth in octave bands
INC	immunonuclear chemistry	LH	luteinizing hormone
INE	intranasal ethmoidectomy	LHRH	leuteinizing hormone-releasing hormone
INO	internuclear ophthalmoplegia	LIF	leukaemia-inhibitory factor
iNOS	inducible nitric oxide synthase	LiNks	Local Involvement Networks (UK)
INR	international normalized ratio; or interventional neuroradiology	LL	lateral lemniscus
		LM	laryngeal mask
IOC	Interim Orders Committee (UK)	LMA	laryngeal mask airway
IOPI	Iowa Oral Performance Instrument	LMN	lower motor neuron
IP ₃	1,4,5-inositol triphosphate	LMW	low molecular weight
IPSS	inferior petrosal sinus sampling	LMWC	low molecular weight compound
IRMA	immunoradiometric assay	LMWH	low molecular weight heparin
IRS	Intergroup Rhabdomyosarcoma Study	LOD	logarithm to the base 10 of the odds that the markers are linked at a recombination distance of <i>N</i> centimorgans
ISAAC	International Study of Asthma and Allergies in Childhood		
ISEL	<i>in situ</i> end labeling	LOH	loss of heterozygosity
ISJ	incudostapedial joint	LOS	length of stay; or lower oesophageal sphincter
ISO	International Standards Organization		
ISS	immunostimulatory DNA sequence	LP	lamina papyracea; or lichen planus; or lymphocyte predominant
ISSNHL	idiopathic sudden sensorineural hearing loss	LPC	linear predictive coding
		LPR	laryngopharyngeal reflux
IT	inferior turbinate	LR	likelihood ratio
ITA	inferior thyroid artery	LREC	local research ethics committee
ITE	in the ear	LSCC	lateral semicircular canal
ITP	idiopathic thrombocytopenic purpura	IT	leukotriene
ITU	intensive therapy unit	ITAS	long-term average spectrum
IUCC	International Union against Cancer	ITASS	long-term average speech spectrum
i.v.	intravenous	LTB	laryngotracheobronchitis; or laryngotracheobronchoscopy
IVIg	intravenous immunoglobulin		
		LTC4-S	leukotriene C4 synthase
JFC	just-follow-conversation	LTR	laryngotracheal reconstruction
JNA	juvenile nasopharyngeal angiofibroma	LTRA	leukotriene receptor antagonists
JORPP	juvenile-onset recurrent respiratory papillomatosis	LVA	large vestibular aqueduct

LVAS	large vestibular aqueduct syndrome	MIDD	maternally inherited diabetes and deafness
LVN	lateral vestibular nuclei	MIP	minimally invasive open
LVOR	linear vestibulo-ocular reflex		parathyroidectomy; or maximum intensity projection; or macrophage inflammatory protein
M	metastases		
MAb	monoclonal antibodies	MIP-1 α	macrophage inflammatory protein-1 α
MABP	mean arterial blood pressure	MISS	minimally invasive sinus surgery
MAC	membrane attack complex; or <i>Mycobacterium avium</i> complex	MIT	moniodotyrosine
MACS	magnetic-activated cell sorter; or minimal access cranial suspension	MIVAP	minimally invasive video-assisted parathyroidectomy
MAF	minimum audible field	ML	mixed cellularity
MALT	mucosa-associated lymphoid tissue	MLD	masking level difference
MAOI	monoamine oxidase inhibitor	MLF	medial longitudinal fascicle or fasciculus
MAP	minimum audible pressure	MLR	middle latency response
MAPK	mitogen-activated protein kinase	MLTB	microlaryngotracheobronchoscopy
MAS	mandibular advancement splint	MM	malignant melanoma
MB	medial bundle	MMC	mitomycin C
MBL	mannose-binding lectin	MMN	mismatch negativity
MBP	major basic protein	MMP	mucous membrane pemphigoid; or matrix-metalloprotease
MBS	modified barium swallow	MMR	measles, mumps and rubella
MCP	monocyte chemotactic protein	MMS	Moh's micrographic surgery
MCP-1	monocyte chemotactic protein-1	MND	motor neurone disease
MCS	mental component summary	MNG	multinodular goitre
M-CSF	macrophage-colony stimulating factor	MOC	medial olivocochlear
MCV	mean corpuscular volume	MODS	multiple organ dysfunction syndrome
MDC	macrophage derived chemokine	MOT	malignant odontogenic tumour
MDR	multiple drug resistance	MPA	microscopic polyangiitis
MDRTB	multidrug resistant tuberculosis	MPL	monophosphoryl lipid A
MDS	myelodysplastic syndrome	MPO	myeloperoxidase
MDT	multidisciplinary team	MPT	maximum phonation time
MDVP	Multidimensional Voice Program	MPTP	1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
ME	middle ear		
MEE	medial edge epithelium	MR	magnetic resonance
MEG	magnetoencephalography	MRA	magnetic resonance angiography
MEK	MAPK/extracellular signal related kinase	MRC	Medical Research Council (UK)
MELAS	mitochondrial encephalopathy, lactic acidosis and stroke-like episode	MREC	multicentre regional ethics committee
		MRI	magnetic resonance imaging
MEMS	microelectromechanical system	MRL	minimal response level
MEN	multiple endocrine neoplasia	mRNA	messenger ribonucleic acid
MERRF	myoclonic epilepsy and ragged red fibre	MRND	modified radical neck dissection
MeSH	medical subject heading	MRS	Melkersson-Rosenthal syndrome; or magnetic resonance sialography
MESS	microscopic endonasal sinus surgery		
MET	middle ear transducer	MRSA	methicillin-resistant <i>Staphylococcus aureus</i>
MF	middle fossa	MRV	migraine-related vestibulopathy
M-FISH	multifluor FISH	MS	multiple sclerosis
MFR	mean airflow rate	MSA	multiple systems atrophy
MGB	medial geniculate body	MSBOS	maximum surgical blood ordering schedule
MGSA	melanoma growth stimulating activity	MSG	monosodium glutamate
MGUS	monoclonal gammopathy of uncertain significance	MST	maximal stimulation test
		MT	maxilloturbinal; or middle turbinate
MHC	major histocompatibility complex	MTC	medullary thyroid carcinoma
MI	myocardial infarction	MTD	muscle tension dysphonia
MIBG	metaiodobenzylguanidine; or iodine-123-metaiodobenzylguanidine	mtDNA	mitochondrial DNA
		MTHFR	methylenetetrahydrofolate reductase
MIBI	sestamibi; or technetium-99m	mTHPC	meso-tetra (hydroxyphenyl) chlorin
MIC	minimum inhibitory concentration	MUS	medically unexplained symptom

MV	mechanical ventilation	NMCC	nasal mucociliary clearance
MVN	medial vestibular nuclei	NMDA	N-methyl-d-aspartate; or National Minimum Data Set (UK)
N	nodal	NNE	normalized noise energy
NA	noradrenaline	NNT	number needed to treat
NADP	nicotinamide adenine dinucleotide phosphate	NO	nitric oxide
NADPH	reduced form of nicotinamide adenine dinucleotide phosphate	NO ₂	nitric dioxide
NAL	National Acoustic Laboratories (Australia)	NOE	naso-orbito-ethmoid
NAMCS	National Ambulatory Medical Care Survey (USA)	non-REM	nonrapid eye movement sleep
NANIPER	nonallergic noninfectious perennial rhinitis	NOS	not otherwise specified
NARES	nonallergic rhinitis with eosinophilia syndrome	NP	nasopharynx; or nasopharyngeal
NATA	National Anonymous Tonsil Archive	NPC	nasopharyngeal cancer; or nasopharyngeal carcinoma
NBCA	n-butyl-2-cyanoacrylate; or N-butyl-cyanoacrylate	NPSA	National Patient Safety Agency (UK)
NBT	nitro blue tetrazolium	NPTA	National Prospective Tonsillectomy Audit (UK)
NCAA	National Clinical Assessment Authority (UK)	NPV	negative predictive value
NCAS	National Clinical Assessment Service (UK)	NPY	neuropeptide Y
NCASP	National Clinical Audit Support Programme (UK)	NRA	nucleus retroambigualis
NCCG	non-consultant career-grade	NRLS	National Reporting and Learning System (UK)
NCCN	National Comprehensive Cancer Network	NRT	neural response telemetry
NCDB	National Cancer Data Base (USA)	NS	nodular sclerosing
NCEPOD	National Confidential Enquiry into Patient Outcome Death (UK)	NSAID	nonsteroidal antiinflammatory drug
NCIC	National Cancer Institute of Canada	NSCAG	National Specialist Commissioning Advisory Group (UK)
NEET	nose, ear, eye and temple	NSF	national service framework
NESSTAC	North of England and Scotland Study on Tonsillectomy and Adenoidectomy in Children	NSHPT	neonatal severe hyperparathyroidism
NET	nerve excitability test	NSRAN	nonsyndromic recessive auditory neuropathy
NFκB	nuclear factor kappa B	NT	nasoturbinal
NF1	neurofibromatosis type 1	NTD	neural tube defect
NF2	neurofibromatosis type 2	NTM	non-tuberculous mycobacteria
NFA	nonfunctioning pituitary adenomas; or nasofrontal approach	NTS	nucleus tractus solitarius
NG	nasogastric	NYHA	New York Heart Association
NH	normal hearing	O ₃	ozone
NHL	non-Hodgkin's lymphoma	OAE	otoacoustic emission
NHS	National Health Service (UK)	OAN	olfactory neuroblastoma
NHSP	Newborn Hearing Screening Programme	OAS	oral allergy syndrome
NIBP	automatic noninvasive blood pressure	OB	olfactory bulb
NICE	National Institute for Health and Clinical Excellence (UK)	OCB	olivocochlear bundle
NICU	nonimmunological contact urticaria; or neonatal intensive care unit	OCFC	open controlled food challenge
NIDDM	noninsulin dependent diabetes mellitus	OCT	optical coherence tomography
NIH	National Institutes of Health (USA)	ODI	oxygen desaturation index
NIHL	noise-induced hearing loss	ODT	olfactory detection threshold
NIPF	nasal inspiratory peak flow	OEC	olfactory ensheathing cell
NIS	Na ⁺ /I ⁻ symporter	OFG	orofacial granulomatosis
NK	natural killer	OGTT	oral glucose tolerance test
N/m ²	Newtons/square metre	OHC	outer hair cell
		OHL	oral hairy leukoplakia
		OHS	obesity hypoventilation syndrome
		OKN	optokinetic nystagmus
		OM	occipitontal
		OMC	ostiomeatal complex
		OME	otitis media with effusion
		OMENS	orbit, mandible, ears, nerves and soft-tissue

OMIM	Online Mendelian Inheritance in Man	PET	polyethylene terephthalate; or positron emission tomography
OPCS	Office for Population Censuses and Surveys (UK)	PET-CT	positron emission tomography/computed tomography
OPG	orthopantomogram	PF	posterior fontanelle; or cisplatinum/5-fluorouracil
OR	occupational rhinitis	PF4	platelet factor 4
OREP	olfactory event-related potential	PFAPA	periodic fever, aphthous stomatitis, pharyngitis and cervical adenitis
ORL	otorhinolaryngology	PFC	perfluorocarbon
OS	osteosarcoma	PFG	percutaneous fluoroscopic gastrostomy
OSA	obstructive sleep apnoea	PGA	polyglycolic acid
OSAH	obstructive sleep apnoea/hypopnoea	PGE ₁	prostaglandin-E ₁
OSAHS	obstructive sleep apnoea/hypopnoea syndrome	PGI ₂	prostacycline; or prostaglandin I ₂
OSAS	obstructive sleep apnoea syndrome	PGL	persistent generalized lymphadenopathy
OSC	overview and scrutiny committee	pHPT	primary hyperparathyroidism
OSPH	ostium of sphenoid sinus	PI	pulsatility index
OSPL	output sound pressure level	PI3-K	phosphatidylinositol 3
OTOF	otoferlin	PICA	posterior inferior cerebellar artery
OVAR	off-vertical axis rotation	PICU	paediatric intensive care unit
P	phosphate; or posterior	PIF	prolactin release inhibiting factor
PA	pernicious anaemia	PIFR	peak inspiratory flow
PAC	P1 artificial chromosome; or pulmonary artery catheter	PIHA	partially implantable hearing aid
PAD	preoperative autologous deposit	PIII	parathyroid III
PAF	platelet-activating factor	PIV	parainfluenza virus; or parathyroid IV
PAG	periaqueductal grey matter	PIVC	parietoinsular vestibular cortex
PAI-1	plasminogen activator inhibitor type 1	PLA	polylactic acid
PALS	Patient Advice and Liaison Service (UK)	PLD	potentially lethal damage
PA-RT	partly accelerated radiotherapy	PLF	congenital perilymphatic fistula
PAS	periodic acid-Schiff	PLG	polylactide-coglycolide
PBP	progressive bulbar palsy	PLMD	periodic limb movement disorder
PCA	patient-controlled analgesia	PLS	primary lateral sclerosis
PCC	prothrombin complex concentrate; or Professional Conduct Committee (UK)	PM	particulate matter
PCD	primary ciliary dyskinesia	PMS	pharyngeal mucosal space
PCHI	permanent childhood hearing impairment	PNP	purine nucleoside phosphorylase; or paraneoplastic pemphigus
PCNA	proliferating cell nuclear antigen	PNS	peripheral nervous system; or postnasal space
PCR	polymerase chain reaction	POGO	prescription of gain and output
Pcrit	critical pressure	PONV	postoperative nausea/vomiting
PCS	physical component summary	PORP	partial ossicular replacement prosthesis
PCT	primary care trust	PP	pyrophosphate
PCTR	partial cricotracheal resection	PPC	Preliminary Proceedings Committee (UK)
PD	Parkinson's disease	PPD	purified protein derivative
PD-ECGF	platelet-derived endothelial cell growth factor	PPI	proton pump inhibitor; or patient and public involvement
PDGF	platelet-derived growth factor	PPRF	parapontine reticular formation; or paramedian pontine reticular formation
PDGFR	platelet-derived growth factor receptor	PPS	parapharyngeal space
PDL	pulsed dye laser	PPV	positive predictive value
PDR	<i>Physicians' Desk Reference</i>	PR3	proteinase 3
PDS	polydimethylsiloxane	PRCT	prospective randomized controlled trial
PDT	photodynamic therapy	PRL	prolactin
PE	polyethylene; or pulmonary embolism; or pharyngo-oesophageal	PRP	platelet-rich plasma
PEEP	positive-end expiratory pressure	PRPP	5-phospho-alpha-D-ribose 1-diphosphate
PEG	percutaneous endoscopic gastrostomy	PRS	persistent rhinosinusitis
PEMA/THFMA	poly (ethylmethacrylate)/tetrahydrofurfuryl methacrylate	PRV	polycythaemia rubra vera

PSA	prostate-specific antigen; or pleomorphic salivary adenoma; or persistent stapedial artery	REM	rapid eye movement
p-SCC	posterior semicircular canal	rEPO	recombinant erythropoietin
PSG	polysomnography	RET	rearranged during transfection
PS-OCT	polarization-sensitive OCT	RFS	rhinofrontal sinuseptotomy
PSP	progressive supranuclear palsy	RFTVR	radiofrequency tissue volume reduction
PSV	peak systolic velocity	RFVR	radiofrequency volumetric reduction
PT	prothrombin time	RHD	Reported Hearing Disability
PTA	pure tone average; or peritonsillar abscess	RI	resistance index
PTC	psychophysical tuning curve	RIA	radioimmuno assay
PTFE	polytetrafluoroethylene	riMLF	rostral interstitial nucleus of the medial longitudinal fasciculus
PTH	parathyroid hormone	RLN	recurrent laryngeal nerve
PTHrP	parathyroid hormone-related protein; or parathyroid hormone-related peptide	RLS	restless leg syndrome
pTNM	pathological tumour, nodes, metastases	RMS	root mean square; or rhabdomyosarcoma
PTP	post-transfusion purpura	RNA	ribonucleic acid
PTS	permanent threshold shift	RND	radical neck dissection
PTU	propylthiouracil	RNID	Royal National Institute for Deaf and Hard of Hearing People (UK)
PU	uncinate process	RNP	ribonucleoprotein
PV	pemphigus vulgaris	ROC	receiver operating characteristic
PVA	polyvinyl alcohol	ROI	region of interest; or reactive oxygen intermediate
PVC	polyvinyl chloride	ROM	range of motion
PVCN	posteroventral cochlear nuclei	ROOF	retro-orbicularis orbital fat
PVP	pause vestibular position; or position vestibular pause	ROS	reactive oxygen species
PVS	persistent vegetative state	RP	rapid prototyping
PZT	lead zirconate titanate	RPA	retropharyngeal abscess
		RPT	rapid pull through
		RR	relative risk
QALY	quality adjusted life year	RRP	recurrent respiratory papillomatosis
QOL	quality of life	RRR	relative risk reduction
QTL	quantitative trait loci	RS	retrosigmoid
		RSDI	Rhinosinusitis Disability Index
RA	retinoic acid	RSOM	rhinosinusitis outcome measure
RAE	Ring, Adair, Elwyn	RSTL	relaxed skin tension line
RAI	radioactive iodine	RSV	respiratory syncytial virus
RALP	right anterior-left posterior	RT	radiotherapy
RAM	Rahmonic amplitude	rT3	reverse triiodothyronine
RANTES	regulated on activation, normal T-cell expressed and secreted	RTK	receptor tyrosine kinase
		RTL	right thyroid artery
RAP	right anteroposterior	rTMS	repetitive low-frequency transcranial magnetic stimulation
RAR α	retinoic acid receptor α gene		
RARS	recurrent acute rhinosinusitis	RT-PCR	reverse transcriptase-polymerase chain reaction
RAS	recurrent aphthous stomatitis		
RAST	radioallergosorbent test	RUDS	reactive upper airways dysfunction syndrome
RAT	rapid antigen testing		
RB	retinoblastoma		
RBC	red blood cell	SACE	serum angiotensin converting enzyme
rCBF	regional cerebral blood flow	SAD	supraglottic airway device
RCPCH	Royal College of Paediatrics and Child Health	SAGM	saline-adenine-glucose-mannitol
		SALT	speech and language therapist
RCT	randomized controlled trial	SANS	subacute necrotizing sialadenitis
RDI	respiratory disturbance index	SAP	signalling lymphocyte activation molecule associated protein
REAG	real-ear aided gain	SAPALDIA	Swiss Study on Air Pollution and Lung Diseases in Adults
REAL	Revised European American Lymphoma		
RECD	real ear to coupler difference		
REIC	real ear insertion gain		

s.c.	subcutaneous	SNOMED CT	Systematized Nomenclature of Medicine – Clinical Terms
SCBU	special care baby unit	SNOT	sino-nasal outcome test
SCC	squamous cell carcinoma or cancer; or semicircular canal	SNR	signal-to-noise ratio
SCCA	squamous cell carcinoma antigen	SNUC	sinonasal undifferentiated carcinoma
SCCHN	squamous cell carcinoma of the head and neck	SO ₂	sulphur dioxide
SCD	sickle cell disease	SOAE	spontaneous otoacoustic emission
SCF	stem cell factor	SOC	superior olivary complex
SCID	severe combined immunodeficiency	SOM	secretory otitis media
SCN	severe congenital neutropenia	SOOF	suborbicularis oculi fat
SCUBA	self-contained underwater breathing apparatus	SOS	guanine nucleotide exchange factor (son of sevenless)
ScvO ₂	central venous oxygen saturation	SP	substance P; or summing potential
SEAC	Spongiform Encephalopathy Advisory Committee	SPECT	single photon emission computed tomography
SEM	scanning electron microscopy	SPET	single photon emission tomography
sEMG	surface electromyography	SPF	sphenopalatine foramen
SF-36	Medical Outcome Study Short-Form 36-Item Health Survey	SPI	soft phonation index
SfBH	Standards for Better Health (UK)	SPIO	superparamagnetic iron oxide
SFF	speaking fundamental frequency	SPL	sound pressure level
SFOAE	stimulus frequency otoacoustic emission	SPT	skin prick test; or station pull through
SGC	spiral ganglion cell	SRS	subacute rhinosinusitis
Shh	sonic hedgehog	SRS-A	slow reacting substance of anaphylaxis
SHO	senior house officer	SRT	speech recognition threshold; or speech reception threshold
SHOT	serious hazards of transfusion	SSC	superior semicircular canal
SIADH	syndrome of inappropriate antidiuretic hormone	SSEP	steady-state potential
SIDS	sudden infant death syndrome	SSG	split skin graft
sIg	surface immunoglobulin	SSLP	simple sequence length polymorphism
SIGN	Scottish Intercollegiate Guidelines Network	SSNHL	sudden sensorineural hearing loss
SIMEHD	semi-implantable middle ear electromagnetic hearing device	SSPE	subacute sclerosing panencephalitis
SIP	sickness impact profile	SSPL	saturation sound pressure level
SIR	speech intelligibility rating; or standardized incidence ratio	SSR	steady-state response
SIRS	systemic inflammatory response syndrome	SSRI	selective serotonin reuptake inhibitor
SL	sensation level	ST	superior turbinate
SLD	sublethal damage	STAT	signal transducer and activator of transcription
SLE	systemic lupus erythematosus	STD	standard deviation
SLIT	sublingual immunotherapy	STIR	short time inversion recovery
SLN	superior laryngeal nerve	STRP	short tandem repeat polymorphism
SLNB	sentinel lymph node biopsy	SUV	standardized uptake value
SLP	superficial lamina propria	SVCO	superior vena caval obstruction
SLT	speech and language therapist	SVL	strobovideolaryngoscopy
SMAS	superficial or subcutaneous musculoaponeurotic system	SVN	superior vestibular nuclei; or superior vestibular nerve
SMOFIT	submucous resection of the turbinate	SVV	subjective visual vertical
SMR	submucosal resection	SVZ	subventricular zone
SMS	short message service; or indium-111 pentetreotide	SWS	slow wave sleep
S/N	speech-to-noise	T	thymine; or tumour
SNC	sinonasal cancer	T1WI	T1-weighted images
SNHL	sensorineural hearing loss	T2WI	T2-weighted images
SNOMED	Systematized nomenclature of medicine	T3	triiodothyronine
		T4	thyroxine
		T/A	tonsillectomy and/or adenoidectomy
		TAGVHD	transfusion-associated graft-versus-host disease

TARC	thymus and activation-regulated chemokine	TRALI	transfusion-related acute lung injury
TARGET	Trial of Alternative Regimens in Glue Ear Treatment	TRAM	transverse rectus abdominis myocutaneous
TB	tuberculosis; or <i>Mycobacterium tuberculosis</i>	TRH	thyrotropin-releasing hormone
TBG	thyroxine-binding globulin	tRNA	transfer ribonucleic acid
Tc	T cytotoxic	TRP	transient receptor potential
Tc-99m	technetium	TRT	tinnitus retraining therapy
Tc-99m (v) DMSA	pentavalent dimercaptosuccinic acid	TSG	tumour suppressor gene
TC	thyroid cartilage	TSH	thyroid-stimulating hormone; or thyrotropin
TCF	tracheocutaneous fistula	TSHoma	TSH-secreting adenoma
TCI	target-controlled infusion	TSS	transitional space surgery
TCP	tricalcium phosphate	TT	thrombin time
TCR	T cell receptor	TTN	thalamic taste nucleus
TdT	terminal deoxynucleotidyl transferase	TTP	thrombotic thrombocytopenic purpura
TEC	Tissue Engineering and Regenerative Medicine Centre	TTR	transthyretin
TENS	transcutaneous electrical nerve stimulation	TTS	temporary threshold shift
TEOAE	transient evoked otoacoustic emission	TUNEL	TdT-mediated nick end labelling
TEP	tracheo-oesophageal puncture	TXA ₂	thromboxane A ₂
TFG	temporalis fascia graft	U	uracil
TFT	thyroid function test	UADT	upper aerodigestive tract
TG	thyroglobulin	UARS	upper airway resistance syndrome
TGF	transforming growth factor	UCL	uncomfortable loudness level
TGF- α	transforming growth factor alpha	UICC	International Union Against Cancer
TGF- β	transforming growth factor beta	UK-CCSG	United Kingdom Children with Cancer Study Group
TGF- β 1	transforming growth factor beta 1	UKCISG	UK Cochlear Implant Study Group
Th	T helper	UMN	upper motor neuron
TIA	transient ischaemic attack	UMP	uridine monophosphate
TIBC	total iron binding capacity	UNICEF	United Nations Children's Fund
TICA	totally implantable cochlear amplifier	UOS	upper oesophageal sphincter
TKI	tyrosine kinase inhibitor	UP	uncinate process
TM	tympenic membrane	UPP	uvulopalatopharyngoplasty
TMC1	transmembrane channel-like gene 1	UPPP	uvulopalatopharyngoplasty
TMD	temporomandibular disorder	UPSIT	University of Pennsylvania Smell Identification Test
TMJ	temporomandibular joint	URT	upper respiratory tract
TMTF	temporal modulation transfer function	URTI	upper respiratory tract infection
TN	trigeminal neuralgia; or trigeminal nerve	US	ultrasound; or ultrasonography
TNF	tumour necrosis factor	USH	Usher syndrome
TNF- α	tumour necrosis factor alpha	USH1B	Usher syndrome type 1B
TNM	tumour, node, metastasis	USPIO	ultra-small super paramagnetic iron oxide
TOAE	transient evoked otoacoustic emission	UV	ultraviolet
TOE	transoesophageal echocardiography; or <i>Trichophyton</i> , <i>Oidiomycetes</i> and <i>Epidermophyton</i>	uVD	unilateral vestibular deafferentiation
TOF	tracheo-oesophageal fistula	UVPP	uvulopalatopharyngoplasty
TOF-o-gram	tracheo-oesophageal fistulogram	UWQOL	University of Washington Quality of Life Questionnaire
TORP	total ossicular replacement prosthesis	VA	Veterans' Affairs; or vestibular aqueduct
TPA	tissue polypeptide antigen	VAAP	voice activity and participation
TPF	docetaxel/cisplatin/5-fluorouracil; or temporoparietal fascia	VAC	vacuum-assisted closure
TPHA	<i>T. pallidum</i> haemagglutination test; or treponemal haemagglutination	VAM	variation of amplitude
TPI	<i>T. pallidum</i> immobilization	VAS	visual analogue scale; or visual analogue score
TPN	total parenteral nutrition	VATER	vertebral, anal, tracheoesophageal and radial
TPO	thyroid peroxidase; or thyroperoxidase	VCA	viral capsid antigen
Tpot	potential doubling times		
TOM	total quality management		

VCAM-1	vascular cell adhesion molecule-1	VPQ	patient questionnaire of vocal performance
vCJD	variant Creutzfeldt-Jakob disease	VRA	visual reinforcement audiometry
VCR	vestibulocollic reflex	VRE	vancomycin-resistant enterococci
VDRL	Venereal Disease Research Laboratory	V-RQOL	voice-related quality of life
VEES	video endoscopic evaluation of swallowing	VS	vestibular schwannoma
VEGF	vascular endothelial growth factor	VSM	velocity storage mechanism
VEMP	vestibular-evoked myogenic potential	VSR	vestibulospinal reflex
VEP	vestibular evoked potential	VTE	venous thromboembolism
VFSS	videofluoroscopic swallowing study	VVI	vocal velocity index
VHI	Voice Handicap Index	vWD	von Willebrand disease
VHI-10	Voice Handicap Index-10	vWF	von Willebrand factor
VHL	Von Hippel–Lindau	VZV	varicella zoster virus
VHQ	Vertigo Handicap Questionnaire		
VHT	vestibular habituation training	WAS	Wiskott Aldrich syndrome
VILI	ventilator induced lung injury	WBC	white blood cell
VIP	vasoactive intestinal polypeptide	WHO	World Health Organization
VLA	very late activation antigen	WMD	weighted mean difference
VLA4	very late activation antigen 4	WOB	work of breathing
VLDL	very low-density lipoprotein	WP	Woodruff's plexus
VMA	vanillylmandelic acid	WPC	WARN, PAUSE, CHECK
VN	vestibular nuclei; or vagus nerve		
VOC	volatile organic compound	XHIM	X-linked hyper immunoglobulin M
VOG	video-oculography	XLA	X-linked agammaglobulinaemia
VoiSS	voice symptom scale	XLP	X-linked lymphoproliferative syndrome
VOR	vestibulo-ocular reflex		
VORP	vibrating ossicular prosthesis	YAC	yeast artificial chromosome
VORS	vestibulo-ocular reflex suppression	YAG	yttrium aluminium garnate
VPI	velopharyngeal insufficiency

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words molecular biology, genetics, and cell biology.

INTRODUCTION

Molecular biology describes the study of the biochemical processes that govern the behaviour of cells. These processes form the fundamental mechanisms by which cell function, cell-cell interactions and cell turnover are regulated. Disruption of this regulation may lead to disease, whilst an understanding of these mechanisms allows the physician to attempt to predict disease behaviour and to explore methods of restoring this regulation at a molecular level. This chapter reviews the principles of molecular genetics and outlines aspects of the molecular biology of the cell in the context of otolaryngological disease processes and describes some of the techniques that form the backbone of current molecular biology. It should give the reader sufficient background knowledge of molecular biology to understand subsequent chapters discussing the molecular biology of specific otolaryngological conditions.

MOLECULAR GENETICS: DNA STRUCTURE AND FUNCTION

Hereditary information in eukaryotes is stored in the form of double-stranded deoxyribonucleic acid (DNA)

and is referred to as the genome. DNA forms a double-helix structure as a result of hydrogen bonds between complementary pairs of nucleotides, adenine (A) with thymine (T) and cytosine (C) with guanine (G). The nucleotides on each strand are organized linearly in triplets, known as codons. Each specific sequence determines a single specific amino acid, for example ACU specifies threonine. However, as there are more triplet combinations (64) than commonly encountered amino acids (20), some proteins may be represented by different codons (e.g. lysine by AAA as well as AAG) and some codons (UAA, UGA and UAG) are 'stop' codons, constituting a signal for arrest of translation. The overwhelming majority of this DNA (99.9 percent) exists in the cell nucleus as the nuclear genome, which, in the human, is estimated to be 3000 megabase pairs in physical size and encodes 30,000–35,000 genes. The remaining DNA (16.6 kilobase pairs) forms the mitochondrial genome, encoding 37 genes. The mitochondrial genome and its potential role in cancer diagnostics will be discussed later.

Each DNA molecule is packaged into a chromosome by complex folding of the DNA around proteins. Diploid human cells contain 22 pairs of autosomes (1 to 22) and a

pair of sex chromosomes (XX or XY) which determines the sex of the organism. One of each pair of chromosomes is maternally inherited and the other is paternally inherited. Each chromosome has a distinctive shape, size and banding pattern, but have the common appearance of two arms apparently separated by a constriction. The centromere is microscopically recognizable as the central constriction separating the chromosome into a long arm (q for queue) and a short arm (p for petit), but its biological role lies in anchoring the chromosome to the mitotic spindle for segregation during cell division. The ends of the chromosomes are capped by telomeres, which are specialized structures containing unique simple repetitive sequences. They maintain the structural integrity of the chromosome and provide a solution for complete replication of the extreme ends of the chromosome. The conventional nomenclature for chromosomal locus assignment is given by the chromosome number, followed by the arm and finally the position on the arm, for example, 3p21 indicates position 21(two-one) on the short arm of chromosome three.

During normal cell division, DNA replication is achieved by the separation of the two strands by DNA helicase. Each separated single strand then acts as a template for polymerization, catalyzed by DNA polymerase, of nucleotides forming a new complementary strand and thus double-stranded DNA identical to the original dsDNA. As each daughter DNA consists of one original and one newly synthesized DNA strand, the process is known as semi-conservative replication. The specificity of the complementary relationship between the nucleotides on each strand forms the basis for many techniques of modern molecular biology and molecular cytogenetics.¹ The accuracy with which DNA replication takes place is remarkable with an estimated error rate of less than one in 10^9 nucleotide additions. Such accuracy is of vital importance to the individual as a permanent change in DNA, or mutation may cause inactivation of a gene essential to cell survival or cell cycle control. The high fidelity of DNA sequence replication is achieved by unidirectional 5'-to-3' direction of DNA replication, a rigorous DNA proofreading mechanism which detects mismatched DNA and efficient DNA repair pathways which excise and repair DNA damage. Failure of these mechanisms, such as is encountered in xeroderma pigmentosum, Fanconi's anaemia and ataxia telangiectasia, leads to accumulation of DNA replication errors and a high incidence of malignancies.

Although the human nuclear genome is 3×10^9 base pairs in size, about 90 percent of it is noncoding, with all the genes being coded by the remaining 10 percent of the DNA. Within the noncoding DNA are dispersed short arrays of repeat units of pairs or triplets of nucleotides (di-/trinucleotides). The exact function of these microsatellite repeats is not entirely clear, but their existence and frequency of dispersion throughout the genome have greatly facilitated study of the genetics of

tumours and many inherited disorders, which will be discussed later.

A gene is a region of the chromosomal DNA that produces a functional ribonucleic acid molecule (RNA). It comprises regulatory DNA sequences which determine when and in which cell types that gene is expressed, exons which are coding sequences and interspersed introns which are noncoding DNA sequences. These regulatory sequences often consist of CpG islands, short stretches of DNA rich in dinucleotides of cytosine and guanine. The methylation status of these CpG islands determines whether that gene is expressed in a particular cell or tissue, being unmethylated in tissues where the genes are expressed. As will be discussed later, aberration of this control is one of the mechanisms of tumour suppressor gene inactivation. Transcription is the intranuclear process driven by RNA polymerase whereby one of the two DNA strands acts as a template for the synthesis of a single RNA strand which is complementary to the DNA, except that uracil replaces thymine in RNA. This primary RNA transcript then undergoes post-transcriptional processing, or splicing.² Traditional dogma held that one gene produces one protein and therefore splicing was considered to occur simply in order to remove the noncoding intronic sequences, producing messenger RNA (mRNA). It is now known that by 'alternative splicing', one gene can result in the production of several different but often related proteins in different tissues.³

The mature mRNA then migrates into the cytoplasm where it acts as a template for the synthesis of a polypeptide during translation, a process regulated and catalyzed by cytoplasmic ribosomes. Successive amino acids are added to the polypeptide chain according to the triplet code on the mRNA, which is recognized by the transfer RNA (tRNA), to which each corresponding amino acid is covalently bound. Translation is commenced upon recognition of an initiation codon (usually but not exclusively AUG/methionine) and terminated upon recognition of a stop codon. The polypeptide subsequently undergoes a variable degree of post-translational modification and/or cleavage to produce the mature protein product, which may have an intracellular role or may be exported to the endoplasmic reticulum and hence to the extracellular space to execute its function.

The mitochondrial genome is considerably smaller than the nuclear genome, but it deserves mention here because of the increasing recognition of the role of mitochondrial DNA (mtDNA) mutations in human disease. The mitochondrial genome is only 16.6 kb in size, comprising 37 genes, which encode polypeptides which are principally involved in the respiratory chain. mtDNA is double-stranded but does not form a double-helix nor does it form chromosomes, but instead it takes the form of a circular double-stranded DNA structure with a heavy and a light strand. Unlike the nuclear

genome, which is inherited from mother and father, the mitochondrial genome of an individual is entirely maternally inherited.

KEY POINTS

- The double-stranded alpha helical structure of DNA, mainly located in the nucleus, consists of nucleotide triplets called codons which code for specific amino acids and stop signals, and forms the substrate for hereditary information in eukaryotes.
- The 22 pairs of autosomes and one pair of sex chromosomes, each with their distinctive shape, size and banding pattern, represent a complex folding of DNA around proteins to give the characteristic shape of a central constriction (centromere) separating the chromosome into a long arm (q) and a short arm (p) with a telomere cap at each end to maintain structural integrity.
- Chromosome locus nomenclature: chromosome number – 3p21 – position on chromosome arm.
- Semiconservative replication of DNA during normal cell division results in the separation of two strands of DNA by DNA helicase, each strand then acting as a template for polymerization by DNA polymerase. High fidelity is vital to prevent permanent change or mutations.
- A gene is a region of chromosomal DNA which produces functional RNA consisting of:
 - regulatory DNA sequences;
 - exons, which are coding sequences;
 - introns, which are noncoding sequences.
- Transcription is the intranuclear process driven by RNA polymerase whereby one of the two DNA strands acts as a template for single-stranded RNA synthesis complementary to the DNA, except that in RNA U is replaced by T. Splicing refers to post-transcriptional processing of RNA.
- Translation is the cytoplasmic process in which mRNA acts as a template for the synthesis of polypeptide by adding successive amino acids to the polypeptide chain, according to the triplet codon of the mRNA which is recognized by the tRNA to which the corresponding amino acid is covalently bonded. This process is regulated and catalyzed by cytoplasmic ribosomes. Post-translational modification produces mature proteins.

METHODS IN MOLECULAR BIOLOGY

Basic techniques of DNA fragmentation and identification

Unlike RNA, DNA is extremely stable, which is understandable from the function that each has in the cell. For purposes of studying the DNA and in order to clone specific DNA, the DNA molecule needs to be divided into manageable fragments. Although the ability to cut (and also to join up) DNA molecules now appears to be a very straightforward process, it was only 1970 when the first restriction endonuclease was identified in a strain of *Haemophilus influenzae*, hence its name *HindII* (pronounced Hin-dee-two). It is believed that this restriction endonuclease acts *in vivo* in bacteria as an immune or host-defence system, recognizing non-self DNA in bacteriophages and cleaving them. By surveying many different bacteria, a wide range of restriction endonucleases is now available, each of which recognize specific target sites based on sequences of four to eight nucleotides. As a specific, seven nucleotide sequence (heptanucleotide) will occur less frequently than a four nucleotide sequence (tetranucleotide), statistically, endonucleases recognizing heptanucleotide targets will cut less frequently thereby yielding larger fragments than those recognizing tetranucleotides. As the DNA is double-stranded, the resultant fragments may have blunt ends or cohesive ('sticky') ends (Figure 1.1). The nature of the ends of DNA fragments thus generated impact upon the way in which they can be ligated (joined) into recombinant molecules. Ligation of DNA fragments with cohesive ends is more efficient than joining of blunt-ended fragments.

ELECTROPHORESIS

Negatively charged phosphate groups on the DNA backbone confer a net negative charge on linear DNA. This allows fragments of different sizes to be resolved within a suitable gel matrix by the application of an electric current across the matrix. The DNA will migrate toward the positive electrode with the smaller fragments travelling faster than the larger fragments.⁴ The size of the fragment can be estimated by the use of a graduated DNA

Figure 1.1 DNA cleavage by restriction endonucleases. Derived from Ref. 11, with permission.

ladder containing fragments of known molecular weight. The choice of the particular matrix depends on the fragment sizes that one is trying to resolve. Polyacrylamide gels can resolve differences of just one base pair between fragments of several hundred base pairs in size by virtue of a small pore size in the gel matrix. These gels can be used for DNA sequencing and resolution of alleles varying in only one dinucleotide repeat. Agarose gels can resolve fragment sizes from around 100 bp to 20 kb. Beyond that size, electrophoretic mobility is no longer proportional to fragment size. Resolution of fragments sizes in excess of 50 kb, such as larger bacterial artificial chromosomes (BAC) or yeast artificial chromosomes (YAC) require the use of pulsed field electrophoresis.

HYBRIDIZATION

Hybridization is the specific annealing of single DNA (or RNA) strands, the probe, to a DNA sample, the target. It serves to detect the presence of a specific sequence of DNA either in the cell or on a hybridization membrane and recognition that hybridization has occurred is achieved either by radioactively labelling the probe and localizing the radioactivity by autoradiography or by labelling the probe with fluorochromes which fluoresce when excited by light of specific wavelengths (**Figure 1.2**). Hybridization on a membrane requires the initial transfer of DNA on to a nitrocellulose membrane from an agarose gel. This elegantly simple process is eponymously known as Southern blotting after the scientist who described the process in 1975. Two other commonly used transfer techniques have their names derived from Southern blotting as jargon terms. Northern blotting is essentially the same process used for transfer of RNA to a membrane. Western blotting is one of the mainstays of protein analysis and involves the transfer of electrophoresed protein bands from a polyacrylamide gel on to a nitrocellulose or nylon membrane to which they bind strongly. Detection of the protein is usually achieved by the use of antibodies to specific antigens presented by the protein with the antibody being labelled radioactively, enzymatically or fluorescently.

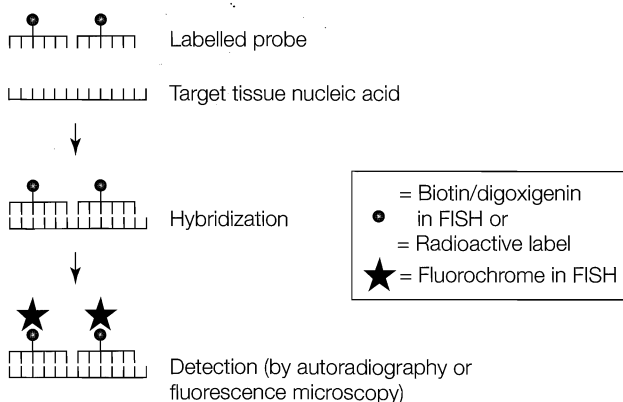

Figure 1.2 *In situ* hybridization.

CYTOGENETICS AND MOLECULAR CYTOGENETICS

Although microscopy had already reached high levels of resolution in the early 1930s, the correct number of human chromosomes was not determined until 1958. The era of classical cytogenetics was thus begun. Cytogenetics is the study of chromosomal abnormalities and rearrangements. It currently has a major role to play in prenatal diagnosis of Down's syndrome and other congenital syndromes characterized by numerical chromosomal abnormalities. In the early part of this century, Theodore Boveri proposed that cancer arose from chromosomal alterations. This hypothesis was not proven until the consistent chromosomal translocation, t(9;22), was demonstrated in chronic myeloid leukaemia. Since that time, cytogenetic analysis has been the mainstay of genetic analysis in reticuloendothelial malignancies, being responsible for the identification of consistent translocations in different leukaemias. Its use in solid tumours has been hampered by the difficulties of establishing short-term primary cultures from head and neck cancers for chromosomal analysis and the erratically acquired chromosomal changes in long-term cell lines, which may have occurred *in vitro*, influenced by culture conditions. Nevertheless, some studies have identified chromosomal areas consistently showing frequent breakpoints suggesting the location of putative tumour suppressor genes (including 3p21, 5p14, 8p11, 17p21, 18q21) and gain or amplification implying the presence of putative proto-oncogenes at other sites (including 3q, 5p, 8q, 11q13). Although the refinement of karyotyping has been radically enhanced by the introduction of 24-colour combinatorial multicolor FISH (M-FISH), the resolution and therefore utility of solid tumour karyotyping remains limited.⁵

Hybridization to target DNA in cells, using fluorescence detection, is known as fluorescence *in situ* hybridization (FISH). Fluorescence *in situ* hybridization allows the analysis of copy number of a known specific DNA sequence within intact nuclei. In reticuloendothelial malignancies and solid tumour-derived cell lines, the use of both single-copy probes and centromere alpha-satellite repeat probes on metaphase preparations has enhanced and refined classical karyotyping. Interphase FISH has been applied to solid tumour sections to assess the copy number of a known sequence in breast, prostate, bladder, brain, lung and head and neck tumours.

Fluorescence-labelled hybridization has also been combined with cytogenetics to produce the powerful technique of comparative genomic hybridization (CGH).⁶ Comparative genomic hybridization permits the rapid medium resolution screening of the entire genome by comparatively hybridizing matched tumour and normal DNA from a patient, which are labelled with different fluorochromes, on to normal metaphase chromosome preparations. Under red-green dual filter fluorescence microscopy and computer-aided image analysis, areas of

genetic 'neutrality' appear yellow, under-representation appears green, and over-representation appears red. Areas of genetic under-representation suggest the possibility of a tumour suppressor gene lying within that region while areas of over-representation may indicate the location of a putative oncogene. This technique has been applied to the rapid genetic analysis of many tumour types including squamous cell carcinomas of the head and neck. The advent of molecular cytogenetics has obviated the need for primary short-term cultures and refined the location of chromosomal aberrations in solid tumours.

POLYMERASE CHAIN REACTION

Perhaps the single molecular technique which has had the most dramatic impact on molecular biology has been the polymerase chain reaction (PCR). The original problem lay in obtaining sufficient quantities of a particular DNA sequence such that DNA profiling (e.g. sequencing) and DNA manipulation (e.g. cloning) could be achieved. The only 'requirement' is that the sequences flanking the stretch of DNA of interest is known. With that proviso, PCR achieves faithful and exponential amplification of a specific sequence of DNA by repeated cycles each consisting of dsDNA denaturation, hybridization of specific oligonucleotides (primers) and extension of the polynucleotide by rapidly altering the reaction temperature between segments of each cycle. dsDNA denaturation is achieved by raising the temperature of the reaction to 94°C for 30 seconds, thus disrupting the hydrogen bonds between the strands and exposing the hydrogen bond donor and acceptor groups to allow base pairing. The oligonucleotide primers are then allowed to hybridize to the denatured DNA (annealing) at around 55–65°C for 90 seconds before the reaction temperature is raised to 72°C to permit extension of the DNA strand by DNA polymerase in the presence of deoxynucleoside triphosphates (dNTPs). With each cycle resulting in the

doubling of the copies of the DNA sequence, a 30-cycle PCR taking approximately two hours would amplify a single copy of a DNA sequence 268 million-fold (Figure 1.3). Although the PCR was originally described by Mullis and Faloona in 1987, one practical problem prevented its instant exploitation.⁷ The DNA polymerase used in the original reaction was denatured during the DNA denaturation segment and therefore had to be added after each and every cycle. The solution came in 1989 when Lawyer isolated and characterized the DNA polymerase, Taq polymerase, from the thermophilic bacterium *Thermus aquaticus* which normally resided in temperatures above 95°C.⁸ This polymerase was therefore 'heat resistant' and did not need to be replenished between cycles.

The PCR holds a central position in many molecular biological techniques as well as clinical diagnostic methods. The fundamental principle of DNA amplification has been adapted to amplify messenger RNA and to amplify areas where the initial flanking oligonucleotide sequences are not known. It is often described as a sensitive and powerful technique, but with great power comes the potential for corruption! In theory, a single copy of DNA can be amplified. Therefore, careless experimental technique may lead to contamination of the DNA sample with other DNA (e.g. from the skin of the investigator) and consequently to an artefactual result. The Taq polymerase originally described in the technique does not have proofreading properties, but newer cloned enzymes such as Pfu polymerase incorporates a proof-reading function to increase amplification fidelity for sequencing reactions.

The sensitivity of PCR also presented a problem for the analysis of genetic alterations in certain solid tumours. Squamous cell carcinomas of the head and neck are histologically often characterized by a large stromal element within the tumour. The genetic alterations in the tumour may not be present in the stromal

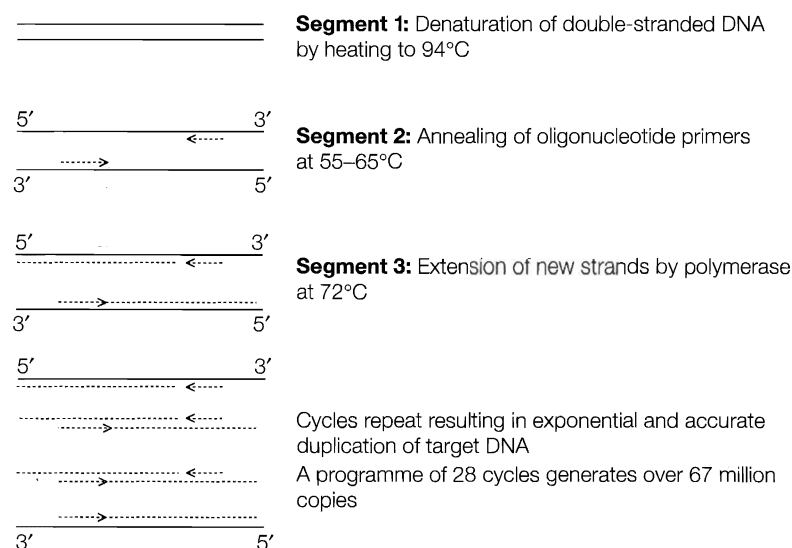

Figure 1.3 The polymerase chain reaction.

tissue and thus total DNA extracted from the tumour will contain DNA from both benign and malignant tissue. This *in situ* contamination can now be eliminated by the use of laser capture microdissection (LCM) of tumours. LCM involves the placement of a laser-activated film over a tissue specimen. When areas of 'pure' tumour cells are identified, a focal laser pulse lifts the tissue on to the film in specimens down to 30 µm in diameter.⁹

KEY POINTS

- Restriction endonucleases are enzymes that were initially identified in bacteria that can cut and join up DNA. They recognize specific target sites based on sequences of four and eight nucleotides.
- Electrophoresis is a technique for resolving the size of DNA fragments, which carry a negative charge from the phosphate groups on their backbone. Using a gel matrix with an electric current applied across it, the DNA will migrate to the positive electrode at a rate inversely proportional to its size.
- Hybridization is the specific annealing of single DNA or RNA strands (probe) to a DNA sample (target) to detect the presence of a specific sequence of DNA in the cell or hybridization membrane. Variants include the eponomously named Southern, Northern and Western blotting techniques.
- Cytogenetics is the study of chromosomal abnormalities and rearrangements important in the diagnosis of congenital syndromes characterized by numerical chromosomal abnormalities, e.g. Downs syndrome and leukaemia types.
- FISH refers to fluorescence *in situ* hybridization which involves hybridization to target DNA cells using fluorescence detection and allows the analysis of copy number of a known specific DNA sequence within intact nuclei.
- PCR achieves faithful and exponential amplification of a specific sequence of DNA by repeated cycles each consisting of:
 - DNA denaturation by heating to 94°C to denature hydrogen bonds between strands;
 - annealing (hybridization) of oligonucleotide primers to denatured DNA at 55–65°C;
 - extension of DNA strand by DNA polymerase.

MOLECULAR ABERRATIONS OF CELLULAR BIOLOGY

Loss of heterozygosity and the expression of recessive mutant alleles

Retinoblastoma is a childhood cancer, which exhibits both hereditary and sporadic occurrence, with the inherited form transmitted as a highly penetrant autosomal dominant trait. The proposition by Alfred Knudson in 1971, based upon a statistical analysis of the occurrence of retinoblastoma in children, that two genetic events were required to inactivate the gene mitigating against development of the cancer, was a major landmark in the understanding of tumour suppressor genetics.¹⁰ In hereditary retinoblastomas, a single additional somatic event in a cell that carried the inherited mutation was sufficient to give rise to the disease while two somatic events were required to produce a sporadic retinoblastoma. This became known as Knudson's 'two-hit' hypothesis. The subsequent study on matched tumour and blood DNA from patients with sporadic retinoblastoma by Webster Cavenee not only proved Knudson's hypothesis but also established the paradigm for all subsequent investigations of tumour suppressor genes.¹¹ For the first time, the now widely accepted mechanisms of tumourigenesis were reconciled, viz. that neoplasms can arise in a multistep manner, that chromosomal events can lead to tumour formation and that chromosome loss with or without reduplication can lead to expression of recessive mutations. Perhaps even more strikingly, the authors presciently suggested that development of homozygosity for recessive mutant alleles at the *Rb-1* locus may give rise to the development of other tumours and that other additional dominant mutations may be involved in the development of retinoblastoma. Cavenee proposed the various chromosomal mechanisms that could reveal recessive mutations and these are summarized for a putative tumour suppressor gene in **Figure 1.4**, adapted from the figure in his original paper. To these can now be added hypermethylation of the 5' CpG island resulting in transcriptional inactivation of the gene, discussed below.¹² The simplest way of revealing a recessive mutant allele is by deletion of the wild-type allele, resulting in hemizygosity at the particular locus on the remaining chromosome. It is inferred from this that areas of frequent allelic loss in tumours may represent the location of putative tumour suppressor genes and this hypothesis underpins the commonly employed method of molecular detection of allelic losses, loss of heterozygosity (LOH).

The practical exploitation of the concepts outlined above hinges on the presence of the previously described microsatellites, highly polymorphic noncoding DNA sequences, also referred to as simple sequence length polymorphisms (SSLP) or short tandem repeat

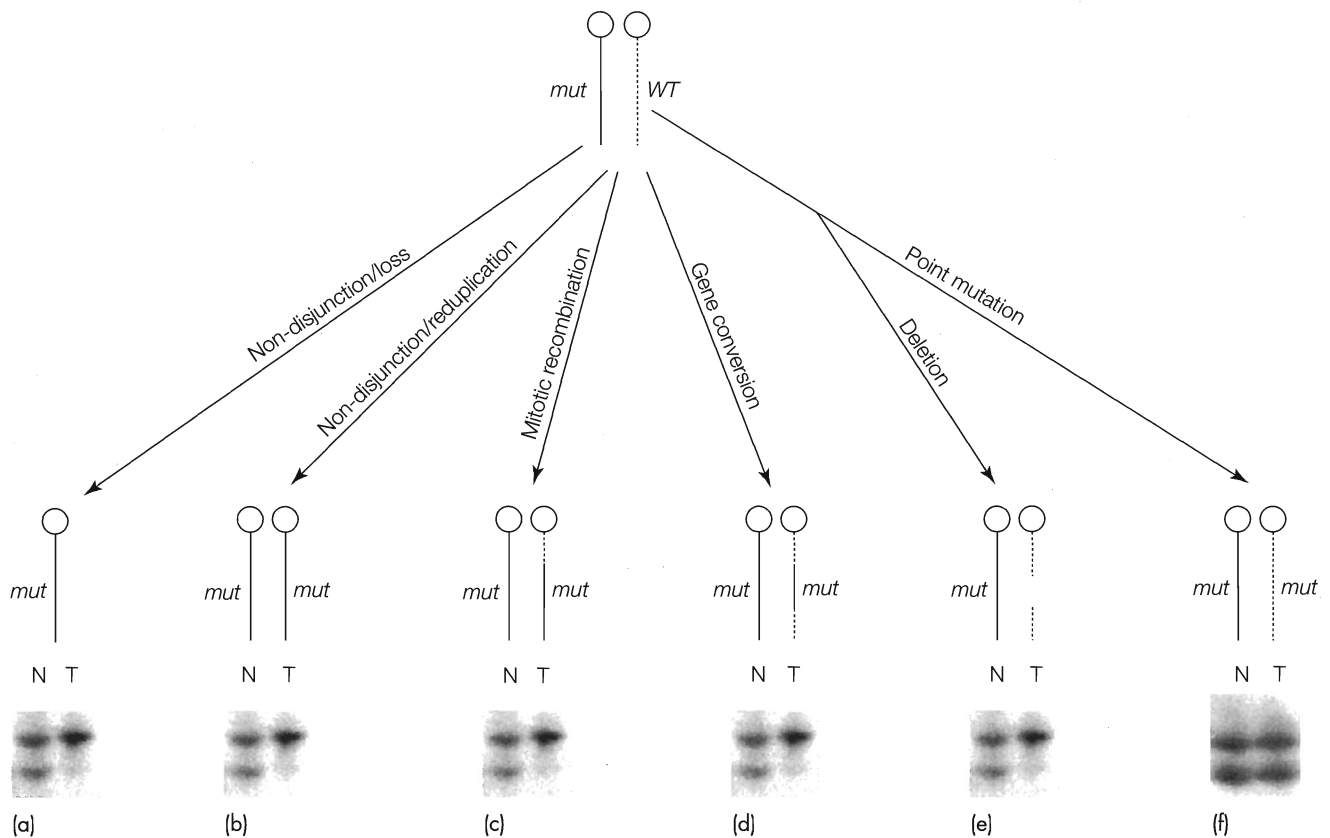

Figure 1.4 Chromosomal mechanisms that could reveal recessive mutations. In this example, before cell division, the tissue concerned carries a mutation in one copy of the hypothetical tumour suppressor gene. In each of the scenarios (a–f), the recessive mutation is revealed. If the individual is heterozygous for a microsatellite marker within or very close to the mutated gene, the hypothetical PCR results are given below each ideotype. The only mechanism which escapes observed loss of heterozygosity is F. *mut*, mutated; N, normal; T, tumour; WT, wildtype. After Ref. 11, with permission.

polymorphisms (STRP), which are distributed approximately every 100,000 bp throughout the human genome. These microsatellites contain small dinucleotide or trinucleotide repeat units, the number of which may differ between the two alleles in a particular person. Microsatellite markers are now available which map thousands of these sequences to chromosomal loci. When DNA sequences containing these microsatellite markers are amplified by PCR in a person heterozygous for that particular microsatellite, the PCR will yield two products of different lengths, which can be resolved on an electrophoretic gel. Where amplification of tumour DNA from such a subject yields only one product, the tumour is said to show LOH, implying allelic loss. Persons who are homozygous for a particular marker are said to be noninformative for that marker. The concept of examining the variation and extent of allelic deletion in tumours was introduced by Vogelstein in an analysis of colorectal carcinomas and termed allelotyping.¹³ Allelotypes generated in this fashion have identified several areas of frequent allelic deletion from which some of the responsible tumour suppressor genes have been cloned or identified. The most common areas of loss in HNSCC are

at chromosome 9p21, 17p21, 13q14, 4p, 5q21 and several discrete regions on 3p and 8p.^{14,15}

Inactivation of genes and oncogenic transformation

Allelic deletion is only one mechanism by which a copy of a gene can be inactivated. As there are two copies of each gene, inactivation of the gene requires inactivation of both copies of the gene, 'the second hit'. This may occur as a result of a genetic mutation or transcriptional silencing. Conversely, a protooncogene may be converted into an oncogene by a simple increase in the copy number of the gene (gene amplification) resulting in an overproduction of protein or by point mutations that affect the control of protein activity.

Not all mutations result in alteration in function of a gene. DNA mutation may occur as a result of base substitutions, as well as nucleotide insertions and deletions. Insertions and deletions of nucleotides are very rare in coding DNA, but if they occur they may produce a shift in the 'reading frame' which dramatically alters the

coding downstream from the mutation. Base substitution is a more common form of mutation in coding DNA which may have a range of consequences on the function of the gene; a loss of function (e.g. *p53*, *Rb*), a gain in function, often due to stabilization of the active protein (e.g. *c-erbB2*, *K-ras*) or no net functional effect. Since an amino acid may be encoded by different codons with a 'third base wobble', e.g. GUA, GAC, GUG and GUU all encode valine, a substitution of the third base would result in no change to the amino acid. This is known as a silent substitution. At the other extreme is the nonsense mutation, whereby base substitution results in a stop codon which leads to truncation of the polypeptide and a dramatic reduction in function.

Loss of function in the presence of a normal (wildtype) allele may occur as a result of transcription silencing. The methylation status of CpG islands surrounding the promoter regions of genes determines whether a particular gene is expressed within a cell such that methylation of a CpG island 'switches off' the gene that it is regulating. CpG islands regulating housekeeping genes, i.e. genes encoding proteins essential for cell survival, are unmethylated in all cell types whereas those regulating cell-specific genes, e.g. muscle-specific actin gene in muscle cells, are only unmethylated in the relevant cell. Many tumour suppressor genes (e.g. *p16*, *APC*, *RASSF1A*) are now recognized to be inactivated by hypermethylation of the promoter region in malignant tumours.

Proteomics

As the Human Genome Mapping Project powers its way towards a high-resolution sequence of the entire genome, the natural progression of research has been towards the elucidation of the repertoire of proteins that control cell signalling and cell growth. Proteomics, the profiling of proteins in cells and serum by two-dimensional gel analysis separating proteins by charge and mass, by x-ray crystallography and by examination of protein interactions (e.g. with the yeast two-hybrid system) remains a young but rapidly expanding field in both basic and translational research.¹⁶ Proteomics has the ability to identify post-translational modifications, some of which are cancer cell-specific, which would not be detected by genetic or expression profiling. The power of this approach is particularly evident in cancer studies as it has the ability to compare the entire protein pattern of tumour tissue and normal tissue in a manner analogous to comparative genomic hybridization.

Telomerase

Aberration of telomere biology has a now well-recognized role to play in cancer development. The length of the telomere is maintained in germline cells by the

enzyme telomerase that is absent in normal somatic cells.¹⁷ This observation led to the theory that progressive shortening of telomeres with each cell division leads to cell senescence and ageing of the organism. Several mechanisms for this have been proposed. A critical shortening of the telomere may leave a nontelomere free DNA end which signals cell cycle arrest. Telomere loss could also extend to the deletion or inactivation of genes located subtelomerically, again leading to cell-cycle arrest. Two important consequences of critical telomere shortening in cells which survive the cell crisis are genomic rearrangements and chromosomal loss which may in turn lead to malignant transformation. This is particularly relevant to rapidly dividing and regenerating tissues, such as skin and mucosa. Paradoxically, while some of these survivors will subsequently go into cell cycle arrest due to critical telomere length shortening, a proportion will then express telomerase activity. Such activity is capable of cell immortalization by maintaining telomere length indefinitely and its role in cancer is now unquestionable. Telomerase activity has been demonstrated in 80 percent of oral cancers and around 50 percent of oral leukoplakia lesions.¹⁸ Even among premalignant lesions, telomerase activity was associated with degree of dysplasia, suggesting that telomerase activation occurs during the late stage of oral premalignancy. The potential for anti-telomerase drugs as a novel treatment remains promising.

KEY POINTS

- Practical techniques based on loss of heterozygosity of tumour DNA are based on Knudson's two-hit hypothesis which states that two genetic events are required to inactivate the gene mitigating against developing a condition.
- The number of microsatellite repeats, i.e. noncoding base pairs dispersed throughout the genome, may differ between two alleles in the same person making that person heterozygous for that particular allele. If tumour DNA from such a subject when amplified by PCR yields only one product, the tumour is said to show loss of heterozygosity implying allelic loss.
- Inactivation of genes can occur by
 - allelic deletion;
 - genetic mutation;
 - transcriptional silencing;
 - conversion of protooncogene to oncogene due to gene amplification.
- Some mutations do not result in change of function. They can be silent or nonsense mutations.

- Proteomics refers to the profiling of proteins in cells and serum by 2D gel analysis, x-ray crystallography and by examination of protein interactions. This can be used to identify post-translational modifications, some of which are cancer cell specific and are not detected by genetic profiling.
- Critical telomere shortening can lead to both cell cycle arrest and cell immortalization due to expression of telomerase which, for example, has been demonstrated in 80 percent of oral cancers.

MAPPING AND IDENTIFICATION OF GENES ASSOCIATED WITH DISEASE

The traditional approach to understanding the molecular biology of disease was to look for and characterize the abnormal protein. Diabetes mellitus and sickle cell anaemia are two conditions that were elucidated at the molecular level in this way. Finding the protein when present in minute quantities, in an inaccessible site such as the inner ear, or when nothing is known of its mode of action, is however virtually impossible. This is the case with most of the genes involved in cellular growth control and also in inner ear function. Our approach to understanding such conditions relies on determining the chromosomal location, isolating and sequencing the gene so that the structure of the protein can be determined. This is known as the reverse genetic or positional cloning technique.

Strategies employed in determining the sites of these disease genes include cytogenetic analysis, molecular genetic analysis (typically LOH studies) and linkage analysis. Where a clearcut inheritance of a disease can be demonstrated, then linkage analysis can be useful in determining the location of the responsible gene. The key advance that has made this approach increasingly successful has been the construction of a high-resolution linkage map of the entire human genome. This map consists of genetic markers spaced less than 1 centimorgan apart and the process of linkage involves determining which of these the disease gene is close to. Analysis of the coinheritance of the genetic marker and the disease trait in families allows one to determine the probability of their physical proximity or linkage to each other. The statistical probability of linkage is expressed in terms of LOD scores. LOD is short for logarithm to the base 10 of the odds that the markers are linked at a recombination distance of N centimorgans. An LOD score of 3.0 favours linkage while a score of -2.0 effectively rules out linkage.

Successful linkage analysis typically requires large pedigrees with many individuals known to have the disease trait and likewise many confirmed to be free of the

disease. The process involves initial family analysis with clinical evaluation and accurate diagnosis. DNA samples are then obtained from each individual and genotyping and linkage analysis can then be carried out. Linkage and molecular deletion analysis generate genetic markers either side of the disease gene location. These genetic markers can be used to identify 'chunks of genomic DNA' cloned into yeast (yeast artificial chromosomes (YAC)) or bacteria (bacterial artificial chromosomes/P1 artificial chromosomes (BAC/PAC)) and organized into libraries. By a number of methods, these 'chunks' of genomic DNA can be directionally organized to produce a physical map of the region of interest from which candidate disease genes can be identified. The Human Genome Mapping Project has, to a great extent, physically mapped the human genome such that in some cases, when the region of interest is sufficiently small, all genes known to be between the markers can be considered positional candidates. The candidates are then analysed in disease families until one is found that demonstrates mutations in affected individuals.

To facilitate the identification of the disease gene from a number of candidates within a particular region, several strategies are available. One such approach exploits our knowledge of animal models of the diseases that parallel human inherited disorders. Another potential source of candidate genes is to identify and characterize genes that are expressed within a particular tissue. Genes expressed within the cochlea, for example, represent the genes critical for cochlear function and thus are excellent candidates genes for hereditary hearing loss.

KEY POINT

- Strategies employed in determining the sites of disease genes which code for the abnormal proteins include cytogenetic, molecular genetic and linkage analysis.

Deficiencies in current knowledge and areas for future research

Although giant strides have already been made in the delineation of molecular events underlying disease processes, the knowledge of these events is far from comprehensive. A clearly identifiable adenoma-carcinoma sequence facilitated the correlation between genetic and histopathological progression models in colorectal cancer.¹³ Several similar progression models have been proposed in head and neck squamous cell carcinoma evolution from epithelial dysplasia through to frank carcinoma, but the heterogeneity of carcinomas in

different subsites precludes a molecular genetic progression model of equal rigour to that in colorectal cancer. Nevertheless, *p16* and *p53* inactivation have been identified as the two most frequent and critical events in head and neck carcinogenesis. An understanding of the sequence of genetic aberrations that occur in pathogenesis of tumours can assist in the prediction of progression from premalignant conditions to frank malignancy. An example of this is seen in the accumulation of genetic abnormalities in oral epithelium leading to the progression of oral dysplasia to oral squamous cell carcinoma. By analysing for loss of heterozygosity at 19 microsatellite loci in a series of oral dysplastic lesions and oral malignancies, Rosin *et al.*¹⁹ showed that LOH at 3p and/or 9p occurred in virtually all cases of oral dysplasia which progressed to frank malignancy implying a 'gatekeeper' role of genes at those loci in the development of oral cancer, in themselves imparting a 3.8-fold increased relative risk of progression to squamous carcinoma. Furthermore, additional LOH at 4q, 8p, 11q or 17p imparted a 33-fold increased relative risk for developing cancer.¹⁹ In certain cases, molecular genetic profiling has added a new dimension to age-old debates. For example, discordant genetic anomalies in inverted sinonasal papillomas and sinonasal carcinomas lend weight to the opinion that the former does not undergo malignant degeneration into the latter.²⁰

Traditional methods of allelotyping and mutational analysis remain extremely time-consuming and labour-intensive. Recent years have seen the development of gene arrays (or 'gene chips') which allow the rapid assessment of the genetic profile of tumours or cell lines.²¹ cDNA of up to 30,000 genes can be placed in arrays on glass slides on to which DNA and RNA samples can be allowed to hybridize using an automated two-colour fluorescence method for detection.²² Hybridization with DNA can yield extensive genomic information, while hybridization with RNA takes genetic profiling a step further by semiquantitatively analysing the expression of genes rather than simply the presence or absence of the DNA. As the genetic aberrations and pathways associated with specific tumour development become better dissected, 'designer' chips can be produced which allow for screening for known mutations of those involved genes.²³ Array technology has also been married with molecular cytogenetics to produce array-based comparative genomic hybridization, which obviates the need for metaphase chromosome spreads for CGH.

The clinician might be forgiven for an expression of cynicism regarding the 'molecular revolution', feeling that little has changed despite ambitious predictions. The translation of molecular biology research into clinical practice – 'from laboratory to bedside' is without doubt the greatest challenge facing the clinician scientist. Progress so far has been largely at the level of disease classification, premorbid diagnosis and patient

counselling. However, several discrete arms to translational research have hinted at the future role of genetic analysis determining the likely effectiveness of existing anti-cancer treatments. There are also isolated examples of effective novel therapeutic interventions.

Molecular analysis played a vital role in differentiating neurofibromatosis type I from neurofibromatosis type II, and it now seems difficult to understand how we ever confused the two in the first place. Such clarity of diagnosis is also anticipated for many syndromic and nonsyndromic causes of sensorineural hearing loss as the genes are characterized and the clinical features analysed in more detail. This may enable clinicians to determine in which cases hearing loss will be progressive and target monitoring more appropriately. Diagnostic genetic testing will also become increasingly available to families with hereditary hearing loss and clinicians will need to be conversant with the ethical issues of testing and the implications of the results. By characterizing hearing loss at the molecular level we are also developing a greater understanding of inner ear physiology as the critical proteins involved in hearing become elucidated. This may lead to the development of agents able to repair and regenerate the diseased inner ear. The administration of these agents is already being evaluated using miniature infusion pumps.

It is hoped that in the future molecular characterization of tumour tissue will provide for a more accurate diagnosis and prognosis than conventional histopathological analysis. This may lead to a more rational treatment plan based on molecular features. Some genotype-phenotype correlations have already been made, particularly with respect to radio- and chemoresistance in tumours, but which need confirmation with larger sample sizes as to their applicability into clinical practice. Refinement of the staging of tumours by probing of resection margins and the detection of histological subclinical metastatic disease in regional lymph nodes have been elegantly demonstrated by Brennan *et al.*²⁴ at Johns Hopkins. However, the technical complexity of the methodology has precluded its widespread application in the clinical arena. The development of technically simpler but equally sensitive techniques will inevitably render molecular staging routine in oncological practice. Although surveillance for tumour recurrence is less of a problem in the upper aerodigestive tract when compared with intraabdominal malignancies, the emergence of molecular markers in saliva and serum will have a role in follow-up protocols for head and neck cancers.²⁵

A comprehensive understanding of the molecular mechanisms underlying disease processes gives the potential of therapeutic restoration of DNA or protein function, as well as exploitation of the genetic abnormality for targetting of therapy. An example of the latter is the use of ONYX-015. ONYX-015 is an E1B

55-kDa gene-deleted adenovirus engineered to selectively replicate in and lyse *p53*-deficient cells while sparing normal cells. This tumour-targeting property has led to a successful phase II trial of concomitant ONYX-015 and cisplatin/5-FU in the treatment of recurrent HNSCC which indicated substantial objective responses, as well as a high proportion of complete responses.²⁶ Post-treatment biopsies of tumour masses confirmed the replication selectivity of the virus *in vivo*.

A consideration of some of the landmarks in molecular biology, e.g. enzymatic DNA cleavage (1970) and PCR (1987), readily indicates that molecular biology is a relatively young science. However, the rapid development of molecular techniques of such power and diversity as comparative genomic hybridization and gene array technology has permitted the dissection of molecular pathways and the identification of their disruption in disease processes. Some of these processes in specific diseases will be discussed in subsequent chapters. The future in the laboratory lies in the extension of our understanding of these molecular processes and the future in the clinic lies in the exploitation of these molecular techniques in better informing disease classification, staging and treatment:

- Development of a molecular genetic progression model for head and neck squamous cell carcinoma of similar rigour to that for colorectal carcinoma.
- Development of gene arrays or gene chips which allow the rapid assessment of the genetic profile of tumours and can allow semiquantitative analysis of gene expression.
- Designer chips may be produced which allow for screening for unknown mutations of involved genes.
- Potential role for genetic analysis in determining the likely effectiveness of existing anticancer treatments.
- Providing more accurate diagnosis and prognosis than conventional histopathological techniques.
- Potential therapeutic restoration of DNA or protein function, as well as exploitation of a genetic abnormality for targeting therapy, e.g. use of ONYX-015.

SEARCH STRATEGY

The data in this chapter are supported by a large number of PubMed searches using a wide variety of relevant key words, including names of authors, names of syndromes and general terms such as hearing impairment. Key words included genetics, DNA, inheritance, hearing impairment, deafness and balance.

INTRODUCTION TO DNA AND ITS USE

Our genome has a pervasive influence upon all aspects of our lives, including hearing and balance. Each cell in our body contains 23 pairs of chromosomes, one of each pair inherited from our mother and the other of the pair from our father, and each complete set consists of a total of 3,000,000,000 bases (3000 Mb) of deoxyribonucleic acid (DNA). The sequence of these DNA bases has been established to a high degree of certainty and is freely available through the world wide web.¹ Much of the sequence has no known function (yet), but using a variety of techniques it has been estimated that there are probably up to 30,000 genes scattered throughout the genome. A gene can be defined simply as a functional unit, a sequence that can be used by the cell to produce a useful molecule, most frequently a protein. The gene is used to make a copy (transcription into messenger RNA or mRNA) which is then used for translation by the cellular machinery into a string of amino acids to form a protein.

Each run of three bases in the mRNA copy of the gene is called a codon. As there are four different types of base available and three bases per codon, there are a total of 64 different combinations that each determine the addition of a specific amino acid to the end of the growing chain or alternatively will stop the translation at the end of the protein (a stop codon). This specification of a particular amino acid by a string of three bases is called the genetic code.

Genes are sometimes present in the genome as a single contiguous sequence of DNA, but most often they are broken up into smaller stretches (exons) that are separated by stretches of noncoding DNA (introns). The number of exons varies between genes; for example, the *GJB2* gene commonly involved in childhood deafness has only two exons, while the *MYO7A* gene which underlies one form of Usher syndrome has 49 exons, and some very large genes can have over 100 exons. After transcription of the mRNA from the gene, the introns are removed from the copy by splicing. Many genes show

alternative splicing, which means that some mRNA copies (and presumably the proteins constructed using these mRNAs) are made with some exons excluded, or with exons used in different combinations. These variant splice forms may produce proteins that serve different functions in the cell, so the phenomenon of alternative splicing can lead to an enormous diversity of functional molecules from the relatively small number of 30,000 genes.

As a cell differentiates to serve a specific purpose in the body, such as a sensory hair cell or a neuron, it requires a specific set of proteins to carry out its function. Furthermore, the process of development into a specific cell type is driven by the expression (use of a gene to produce a protein by the cell) of particular genes. Thus, it is clear that control of transcription and translation of genes is critical to normal development and function. Many of the genes we study encode transcription factors, which are proteins that influence the transcription and translation (expression) of other genes. We know that some of the noncoding stretches of DNA in the genome have a critical role in this process of control of expression. Therefore, when we search for variations (mutations) in DNA sequences that lead to hearing or balance problems, we need to consider noncoding sequences that may influence gene expression as well as looking for changes in the coding sequences of genes. For example, the *POU3F4* gene is involved in X-linked mixed conductive and sensorineural hearing impairment with gusher, but some of the mutations affecting expression of this gene lie far upstream (900 kb away) of the coding sequence.² Variants in noncoding sequences may control the amount of expression of a gene, the location (which cell types) of expression, or the timing of expression during development.

VARIATION

DNA sequence from different individuals differs at around one base per thousand. This variation is called polymorphism. We are a long way from understanding the consequences of all variations in sequence, but it is reasonable to assume that some of these polymorphisms will influence the development and function of the person. The polymorphisms may consist of a substitution of one base by another, the deletion or addition of one or more bases or of large stretches of DNA, or rearrangements of large chromosomal regions such as inversions. As there are so many variations in DNA sequence between individuals, it is difficult to establish conclusively which of the many differences is responsible for a particular feature, such as hearing impairment. The term mutation is often used to describe a change in DNA that has a deleterious effect, but strictly speaking it can also be used to describe a polymorphism with a beneficial influence.

GENE INTERACTIONS

Genes do not work in isolation. They work in the context of the variations in all the other genes carried by that individual and the environment to which the individual is exposed. Thus, a person may have a hearing impairment because of a mutation in a single gene, or because they carry two or more variations in genes that together contribute towards poor auditory function, or because they carry a variation that makes the individual more susceptible to adverse environmental conditions. We know most about the role of single gene mutations in deafness because these are the simplest causes to study as there is only one gene to track down and the mutations often have a clearcut, categorical effect that is easy to ascertain, such as severe or profound deafness.^{3,4,5} Interactions between two or more gene variants are more difficult to study. Phenotypic features associated with variants in several genes are referred to as polygenic features, and the locations (loci) of these variations in the genome are often called quantitative trait loci (QTL) because they each make a contribution to a trait that can be measured (such as auditory thresholds). Finding the causative variations in these situations is usually very difficult because each variant may account for only a small fraction of the measurable trait, such as 10 percent or less. Furthermore, it is thought that many diseases may be influenced by a number of variant genes dispersed amongst the population, so a group of people with the same measurable deficit (for example, the same degree of hearing impairment) may carry different combinations of variant genes making it even more difficult to find each one.

Even in cases where a single gene defect is the primary cause of a hearing impairment, the clinical phenotype may be influenced by variants in other genes, called modifiers, carried in the genetic background of an individual. Modifiers are variants of genes that can either ameliorate or exacerbate the effects of a single gene mutation and they may account for differences in the degree or time of onset of a hearing impairment in two people who carry the same primary deleterious mutation.⁶ We presume the modifiers act in the same molecular pathway as the primary gene. For example, modifiers may lead to increased expression of alternative genes that might be able to compensate to some extent for the abnormal function of the primary gene. A modifier would not necessarily have any obvious effect on hearing in the absence of a primary deleterious mutation.

GENES AND ENVIRONMENT

It is well known that environmental factors, such as excessive noise exposure, drugs like aminoglycosides or diuretics, or infections including meningitis can lead to hearing loss. However, not all people working in the same noisy environment develop the same degree of hearing

loss, and not all children who contract meningitis end up deaf. Why should this be? It has long been suspected that individuals may have a genetic predisposition to damaging environmental factors, and we are now beginning to accumulate evidence for genetic variations that can make a carrier more or less sensitive to damage. The clearest example in humans is the A1555G mutation of the mitochondrial genome, in which the normal base A at position 1555 in the sequence is changed to a G. People carrying this mutation show a greatly increased sensitivity to hearing loss after treatment with aminoglycoside antibiotics.⁷ In mice, we now know of variants in at least four different genes that make the carriers more sensitive to noise-induced hearing loss.⁸ It is clear that we are only just beginning to reveal the role of specific gene variants in making us more or less susceptible to hearing loss triggered by environmental factors, and that there are many more such variants awaiting discovery.

WHAT IS THE CONTRIBUTION OF GENETICS TO HEARING IMPAIRMENT?

Hearing impairment affects all age groups. Around one in 850 children is born with a significant, permanent hearing impairment, and this proportion doubles during the first decade or so of life as further children develop progressive hearing loss.⁹ The number of hearing-impaired individuals increases with each additional decade, until as many as 60 percent of the over 70 age group show a 25 dB or worse permanent threshold loss.¹⁰ Thus, a very large proportion of the population suffers some degree of hearing impairment at some stage of their life.

It is often difficult to give an accurate diagnosis of the cause of hearing impairment in an individual, so any estimates of the relative contributions of genetics and environment in the population must be viewed with caution. Most estimates suggest about half the cases of severe or profound permanent childhood deafness are due primarily to genetic causes.^{11, 12} However, this is likely to be an underestimate of the true contribution of genetics because, as discussed above, it is difficult to disentangle the effects of damaging environmental factors from genetic predispositions. It is likely that all cases of hearing impairment have a genetic contribution of some sort, varying from a major contribution from a deleterious mutation in a single gene that is essential for auditory function to a minor contribution from a genetic variant that makes an individual slightly more sensitive to environmental damage.

What is the contribution of genetics to hearing impairment in older age groups? Often genetics is not considered as a potential major contributor to age-related hearing impairment (presbycusis) and it is true that we currently know very little about the exact causes of later onset progressive deafness in the population. However, there are a number of observations that indicate that

genetics does play a significant role in progressive hearing loss. Firstly, a surprisingly large number of single gene mutations have been found to be associated with late-onset progressive hearing loss.^{3, 13} Some of these mutations have been identified and some only localized to a specific region of the genome. These single genes have been discovered, though the study of large pedigrees in which it is clear that hearing loss is inherited as a single gene defect, mostly as dominantly-inherited mutations (see below under Inheritance). It is a simple and logical step to suggest that a gene shown to be involved in progressive hearing impairment with onset in the 20–50-year age range in some families may have a mutation with a milder effect leading to later onset hearing loss in other families. Thus, the genes already identified as being involved with progressive hearing loss are good candidates to search for milder mutations associated with presbycusis. Secondly, we know from studies of the mouse that there is a strong genetic influence on late-onset hearing loss, and we are starting to identify some of the genes involved in these mice. This is a useful approach because it is much easier to identify a mutated gene in the mouse than in humans because it is possible to generate large numbers of genetically well-defined mice carrying the same mutation for linkage analysis (the method used to localize a mutation to a specific region of a chromosome). Any genes contributing to late-onset hearing loss identified in the mouse represent further good candidates to screen for their involvement in human presbycusis. Mice represent excellent models for human deafness and just about every gene discovered to be involved in deafness in the mouse has later been found to underlie a form of human deafness. Thirdly, there have been several studies published that measure the heritability (the proportion of the variance due to genetics) of auditory function in middle-aged and older human populations, using either twins, siblings or other family groups.^{14, 15, 16} All these studies found relatively large estimates of heritability, from around 30 to 50 percent or more, with the higher frequencies and younger age groups (for example, 40–60 years old) showing greater degrees of heritability than lower frequencies and older age groups. These findings suggest that genetics plays an important role in presbycusis, although it is not yet clear whether each person develops progressive hearing loss because of a single gene mutation, because of the polygenic effects of several genes summed together, or because affected people carry mutations that make them especially sensitive to environmental damage. Indeed, it seems likely that all three mechanisms will contribute to presbycusis in the human population, even if one mechanism is the predominant cause in each individual.

The recognition that genes play a key role in progressive hearing loss is important because it changes the way we view the problem. Having a genetic basis to hearing loss is equivalent to holding a key to the molecular basis of the pathology, because we can use genetics as a tool to identify

the molecules that are involved, a first step to thinking about medical strategies for treatments.

HOW MANY GENES ARE INVOLVED?

It seems likely that hundreds of genes may be involved in hearing impairment. In the case of nonsyndromic deafness (deafness alone, with no other distinguishing feature), we know at least 86 different genes can underlie deafness because we have found this number of different chromosomal locations of mutations associated with deafness.³ Thirty-six of these genes have been identified, so we know the gene involved and the mutations of that gene that lead to hearing impairment, while in the remainder we know only a defined region of a chromosome that must contain the mutated gene, but have not yet identified the mutation that causes the deafness.³ In the case of syndromic deafness (deafness as part of a group of features), over 400 different syndromes that include deafness are listed in Online Mendelian Inheritance in Man (OMIM), the main clinical database of genetic diseases.¹⁷ Although the mutations leading to many of these syndromes have not yet been identified or even mapped to a specific chromosome, the fact that there are so many distinct, inherited syndromes with deafness does suggest that many further genes may be involved in hearing impairment in these cases. An excellent, up-to-date compendium of deafness genes with links to primary references and other useful databases is available on the internet.³

Some genes are involved only rarely in human deafness, while others have a larger role in the human population. For example, mutations in the *GJB2* gene, encoding the gap junction protein connexin 26, are a relatively common cause of severe or profound childhood deafness, accounting for between 25 and 50 percent of children with recessively inherited congenital deafness in some populations.^{18, 19, 20, 21} As we identify more of the genes associated with deafness, it will be important to assess their involvement in the hearing-impaired population at large, in order to develop a rational strategy for diagnosis, looking for the most common mutations first and to prioritize genes for further research.

INHERITANCE

Single gene mutations leading to a clearcut phenotype (like deafness) that is either present or absent may be inherited in several different ways. These patterns are referred to as Mendelian (after Mendel) and a Mendelian pattern of inheritance is usually a good indication that a single gene is involved rather than several genes or a complex interaction between genome and environment. The mutated gene may be located on the X chromosome or on one of the other 22 chromosomes, referred to as autosomes, or may be part of the mitochondrial genome.

The majority of genes are located on an autosome. If only a single copy of the mutation is required to have an effect on the phenotype (for example, a mutation causing Waardenburg syndrome), and the effect of this mutation overrides the action of the normal copy of the gene on the other one of the pair of chromosomes, then the mutation is said to be inherited in a dominant manner. If two copies of a mutant gene are needed to have an effect on the phenotype, one on each of the pair of chromosomes, then the inheritance is termed recessive. People carrying just one copy of a recessively inherited mutant gene will show no obvious effect. If individuals carrying just one copy of a mutant gene (heterozygotes) show a phenotype that is intermediate between those carrying two copies of the normal gene and those carrying two copies of the mutant gene (homozygotes), then the inheritance is called codominant (or semidominant). It may be the case that many mutations that are thought of as dominant are in fact codominant, but individuals with two copies of the mutant gene are rarely, if ever, seen. Autosomal recessive inheritance appears to be the most common pattern of inheritance involved in childhood deafness, while autosomal dominant inheritance often seems to be found in families with later-onset progressive hearing loss.^{3, 13} A typical family with known recessive inheritance will have unaffected parents but one or more affected children, while in typical families with dominantly inherited deafness, one of the parents will have hearing impairment as well as half the children.

Mutations located on the X chromosome are called X-linked. They may be recessive or dominant in their action. However, X-linked mutations show a distinctive pattern of inheritance because males have only one X chromosome and the other of the pair is a Y chromosome containing very few genes. Therefore, males carrying a recessive mutation on their X chromosome will have no normal copy of the gene to compensate, so will show the phenotype. Females have two X chromosomes, so if they carry one copy of the mutant gene, they will usually appear normal because they have a normal copy on their other X chromosome. This leads to an unusual pattern of inheritance: only males will be affected in a family, but the mutation can only be passed on to offspring through a carrier female because males always inherit their X chromosome from their mother and their Y from their father.

Finally, mutations of the mitochondrial genome have been associated with deafness, particularly progressive hearing loss. Mitochondria are intracellular organelles that carry their own small stretch of DNA, with many copies in each cell rather than just two as for the chromosomes. Mitochondrial DNA is inherited only through the mother, not through the father, by being passed on in the cytoplasm of the oocyte. Thus, any mitochondrial mutations will show maternal inheritance, but male and female offspring can be affected equally.

Mendelian patterns of inheritance can be very useful in attributing a phenotype like deafness to a single gene

defect, but they will not pick out all cases in any clinical sample. There are many reasons for this. Firstly, human families are usually relatively small and may be geographically dispersed, making it difficult to draw up and assess a pedigree and the phenotypes accurately. For recessive inheritance, the effect of small family size is that the majority of cases will probably be the first to be affected in the family, as the parents will be carriers and have a normal appearance and more distant relatives are also unlikely to be affected. **One important clue to recessive inheritance in a single deaf child in some families is the relationship between the parents: if they are blood relatives, such as cousins, then it is highly likely that a recessive mutation is the cause of hearing impairment in their child.** There are many different genes involved in deafness, and each is relatively rare, so any degree of common ancestry of the parents increases the likelihood that two copies of the same mutant gene will come together by chance in a child, causing deafness. Secondly, even in dominantly inherited deafness in which each generation should be affected, the hearing impairment in older relatives may have been attributed to other causes, like presbycusis, infection or excessive noise exposure. Many cases of dominant hearing loss show progressive loss, which is often (mistakenly) not thought of as likely to be due to a single gene defect, leading to such misdiagnosis. Dominantly inherited conditions often appear to be quite variable in phenotype, showing variable expression characterized by differing degrees of impairment in affected individuals, or reduced penetrance, in which some carriers of the mutation may not show the impairment at all. Furthermore, some genes seem to be relatively mutable, so that new dominantly inherited mutations can arise *de novo* in a family causing deafness, and these can be passed on to successive generations. These features will all complicate interpretation of the pedigree and make diagnosis of a genetic cause for hearing impairment in an individual difficult.

MAPPING AND CLONING GENES

There has been considerable effort worldwide over the past few years to identify genes involved in deafness,^{3, 4, 5, 22} because an understanding of the molecular basis of hearing impairment is an essential first step in devising treatment strategies using a medical approach. Development of new treatments as an alternative to the imperfect approaches of amplification with hearing aids or cochlear implantation is the primary goal of this genetic research.^{23, 24} **Having a mutation in a single gene associated with deafness is an extremely valuable tool, because it gives us a means to identify a molecule that is essential for normal hearing.** Furthermore, the understanding gained from studying genes involved in deafness will be useful for developing generic treatments for many types of hearing impairment, not just types caused by single gene defects.

How do we go about identifying genes involved in deafness? One approach might be to guess which gene is a likely candidate based upon what we know of the molecules involved in auditory function, and search for mutations in that gene in DNA samples from affected individuals. This is not a useful strategy at the moment, because it is constrained by the very limited knowledge we have of the molecular basis of hearing. There are 30,000 genes to search through, and guessing the right one is too great a gamble for funding agencies to consider. Our experience to date has been that many different classes of genes have been shown to underlie deafness and that few if any of them would have been thought of as a good candidate *a priori*. Even if genomic changes are found in a favourite gene, proving a causal link with deafness is very difficult. Thus, we need to limit the search using additional criteria. Expression is increasingly used as a means of reducing the list of candidate genes, by looking at which genes are transcribed and/or translated into proteins by the cell. However, as each cell type probably will express several thousand genes at different stages in its development, this approach may not reduce the list by very much.

Positional cloning is the usual method used for identifying genes associated with diseases like deafness.²⁵

The term positional simply means using the position of a mutation on a chromosome as a clue, while cloning refers to a way of copying the stretch of DNA of interest which is no longer an essential part of the process but is still a term in common usage; identification is a more accurate term to use for finding the causative mutation. **The first stage of positional cloning is mapping, or localizing, the mutation to a region of a particular chromosome by linkage analysis.** Mapping mutations involves collecting DNA from families showing mendelian inheritance of a phenotype and typing polymorphic markers that span the entire genome (a genome scan) to find chromosomal markers that tend to be inherited with the mutation. This will suggest that these markers are located close to the mutation (linked to the mutation), as the further any marker is from the mutation, the more likely it is to be physically separated from the mutation by crossing over during meiosis. Mapping requires large numbers of family members, some with and some without the phenotype, so most deafness genes that have been identified to date have been mapped first in families from cultures where large numbers of children are common, or in geographically isolated communities. When a restricted region of a chromosome has been defined as containing the mutation, the next step is to look at the genes within that region and prioritize them for detailed mutation screening, usually by sequencing the exons (coding parts) of the genes. There may still be hundreds of genes within the region defined by mapping, so usually researchers look carefully to try to pick out the best candidates for involvement in deafness, and expression in the ear can be useful in suggesting good candidates. When a genomic

change is discovered, further evidence is needed to determine whether it is indeed the mutation causing the pathology, as there are likely to be many genomic variants within the target chromosomal region. If the putative mutation is not found in the unaffected population, it is predicted to have a severe effect on protein structure and the gene is known to be expressed in the ear, this would argue in favour of the mutation being causative. If other mutations in the same gene can be found in affected members of other families or in an animal model like the mouse showing the same phenotype, this would further strengthen the claim.

THE MOUSE AS A MODEL

An animal model is vital for understanding the molecular and developmental basis of deafness, and the mouse is the model of choice.^{26, 27} The mouse is a mammal, with middle and inner ears very similar to human ears, and the many deaf mouse mutants available show similar types of pathological features as their human counterparts. Furthermore, genes found to be associated with deafness in the mouse are with only very few exceptions also found to underlie human deafness, and *vice versa*. Many basic studies such as early developmental analysis, genetic manipulation, damaging noise exposure and so forth are only possible in an animal model, and mice can be bred to provide thousands of individuals for high resolution mapping of deafness genes, making the mouse a valuable model for studying the genetics of deafness.

OTHER OTORHINOLARYNGOLOGICAL DISORDERS

Although this chapter has focussed on hearing impairment in illustrating the basic principles of genetics, other disorders will also be influenced to some degree by genetics. For example, allergic rhinitis shows a strong genetic influence, but it appears that several genes are involved, each contributing to the risk of the carrier developing rhinitis.^{28, 29} No doubt environmental factors play a role in the development of rhinitis as well as the genetic predisposition.

WHAT LESSONS HAVE WE LEARNED FROM GENETIC RESEARCH SO FAR?

Complexity and heterogeneity are the main features. There are many different single genes that can be involved in deafness, probably hundreds of them, and genetic variants contribute to all forms of hearing impairment including sensitivity to environmental damage and age-related progressive hearing loss. Some genes can harbour

different mutations giving either dominant or recessive hearing impairment, others can involve either childhood deafness or progressive, later-onset loss, and yet other genes can underlie both syndromic and nonsyndromic deafness.³ A good example of this level of complication is the *MYO7A* gene and Usher syndrome (USH). Usher syndrome type 1 is characterized by a set of common features: profound childhood deafness, balance dysfunction and progressive retinitis pigmentosa. However, at least seven genes can be involved in this syndrome, four of which have been identified and the others only localized to date.³ The most common cause of USH1 is mutation of the *MYO7A* gene, defined as USH1B. *MYO7A* mutations can also be associated with two forms of nonsyndromic deafness, with no evidence of retinitis pigmentosa: the dominantly inherited DFNA11 with later-onset progressive hearing loss and the recessive childhood deafness, DFNB2.³

Other lessons we have learnt include the finding that some genes are involved in only a small number of cases of deafness, while others (such as *GJB2*) account for a much greater proportion of deafness in the population. The majority of cases of deafness in the population still have no clear diagnosis, suggesting that there are many deafness-associated genes remaining to be found.

Work on mouse models has given us further indications of general features of genetic deafness. Firstly, almost all single gene defects leading to hearing impairment have a primary effect in the middle or inner ears, with very few examples in which a central auditory system defect is the primary cause of the deafness.²⁷ Secondly, although it is commonly thought that hair cell degeneration is a major cause of hearing impairment, work with many mouse mutants suggests that hair cell degeneration is either a correlate or a consequence of a primary dysfunction either of hair cells or another part of the auditory system, rather than a primary cause. Even in cases of noise-induced damage, it seems that auditory dysfunction is more closely associated with stereocilia disruption than with hair cell degeneration.^{8, 30} Hair cells may die later, making the hearing impairment essentially irreversible with current technologies, but it is important to appreciate that hair cell death is secondary to a primary dysfunction when developing new treatment strategies. For example, there is no point in attempting to regenerate hair cells that will not function because of an inherent abnormality. Thirdly, supporting cells are critical to cochlear function, so any approach involving regeneration of hair cells as a treatment must also include regeneration of support cells. Fourthly, many genes involved in deafness are expressed in structures other than hair cells. The *GJB2* gene is a good example of this, as it is expressed in the supporting cell network and spiral ligament of the cochlear duct and not in hair cells. Therefore, any attempts to treat deafness will need to be targeted to the appropriate structures, making accurate diagnosis a critical part of the process.

KEY POINTS

- There are 3,000,000,000 bases of DNA in each set of 23 human chromosomes, including approximately 30,000 genes.
- Variation is very common with sequences differing between individuals at around one base per thousand. This makes it difficult to establish which DNA variant might be the cause of a particular inherited feature, such as deafness.
- Genes interact with the environment; some variants of genes will make us more or less susceptible to environmental insults, such as noise damage.
- Genes also interact with each other in shaping our phenotype.
- Genetic variation makes a major contribution to hearing impairment, including age-related hearing loss which shows a heritability of around 50 percent.
- There are hundreds of genes involved in hearing and balance and any one can be involved in deafness in an individual. In other cases, problems can arise from variants in several genes acting together.
- Many genes involved in deafness are inherited in a Mendelian fashion: dominant, recessive, X-linked or mitochondrial. The collection of large families with affected individuals has allowed us to map the causative mutation to specific chromosomes and then identify the gene and the mutation by a process called positional cloning.
- The mouse is an excellent and very useful model for understanding the genetics and pathology of human deafness.
- Complexity and heterogeneity are the hallmarks of the aetiology of deafness and balance problems.

Deficiencies in current knowledge and areas for future research

Genetics will have an increasing impact on day-to-day clinical practice in the future. Genetic research will lead to new treatment possibilities and improved diagnostic tools over the next 10–15 years. Exactly how this might develop has been discussed in detail elsewhere,^{23,24} but it is clear that clinicians must be at the heart of the process, having genetics at the top of their list when considering causes of hearing impairment and developing close communication with the research community.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words gene therapy, cystic fibrosis, head and neck cancer, gene transfer, adenoviral vectors, adeno-associated vectors, ballistic gene delivery, chemosensitization and retroviral vectors.

INTRODUCTION

Few new treatment protocols seem to reflect the allure of modern science quite as elegantly as gene therapy. The promise of gene therapy in treating a variety of diseases is, simply put, incredible. This promise has captured the hopes and enthusiasm of the scientific and lay communities alike. Notable initial success in treating severe combined immune deficiency (SCID) seemed to herald imminent success in treating a whole variety of other conditions. In reality, however, progress in bringing the allure of the science to a useful clinical application has been quite limited. Even in the group of SCID subjects¹ – an apparent ‘cure’ – a patient has died from an unusual lymphoproliferative disease. This has led to a reassessment of the risks of retroviral therapy trials. While great strides have been made in understanding the complexities of disease states and vectors, the barriers to clinical utility continue to be formidable.

Today, some 63 human clinical trials of gene therapy exist. The disease processes involved can be broadly divided into three groups: infectious disease trials, which entirely comprise human immunodeficiency virus (HIV); secondly, monogenetic diseases such as cystic fibrosis (CF) and hemophilia B and thirdly diseases that are

polygenic such as rheumatoid arthritis or cancer. These studies deliver genetic material to target cells via vectors, which act as delivery vehicles to bypass host defences. In the very select circumstances of the skin or eye, a ‘gene gun’ can be used. The treatment aims to replace or repair the defective gene causing a given disease or to provide a new or altered function in a cell. The most common vectors are a variety of replication-deficient viruses although nonviral vectors, such as liposomes, are also used.

In reviewing progress to date in gene therapy, two diseases of interest to otolaryngologists encapsulate the potential and difficulties of this technique. We will review an apparently attractive candidate for gene therapy, a disease caused by a single mutation inherited in an autosomal recessive fashion – cystic fibrosis.² We will also review progress in a condition with a variety of causalities and a disparate genetic basis, head and neck cancer³ – a superficially unattractive candidate for gene therapy. These two diverse diseases serve to illustrate many of the principles, advances and frustrations of gene therapy. In both these examples, human trials are in their infancy. Trial sample size is small and results so far do not readily lend themselves to the categorization of levels of evidence, as displayed in other chapters in this text.

CYSTIC FIBROSIS

Cystic fibrosis represents a seemingly ideal disease for gene therapy. It is the most common lethal genetic disease of one of the wealthiest racial subgroups in the world. There are perhaps 30,000 people with CF in the United States and a similar number in Europe. It is inherited with an autosomal recessive pattern with carrier rates of 5 percent in some Caucasian populations.⁴ Remarkably, the median survival for CF patients is now 31 years. Unfortunately, the disease remains almost uniformly fatal, invariably from its pulmonary sequelae.⁴ Despite dramatic improvements in the understanding of the molecular basis of CF, there has as yet been no clinically useful breakthrough in its treatment. Clearly, new treatments are needed. Conceptually, gene therapy offers the promise of a dramatic and new treatment.

Genetic basis

The discovery of the gene for CF in 1989⁵ set in motion a remarkable series of events, often covered by the lay press with the hyperbole of popular culture, which have culminated in attempts at gene therapy. CF is caused by mutations in a gene on the long arm of chromosome 7. This gene encodes a protein, cystic fibrosis transmembrane conductance regulator (CFTR), which has been shown to be a cAMP-dependent chloride channel.⁶ Abnormalities of CFTR produce abnormalities of salt and water transport across a variety of epithelia. This produces the various manifestations of the disease. The deletion of a single phenylalanine residue at position 508 of CFTR, designated $\Delta F508$, is the most common mutation in cystic fibrosis comprising some 70 percent of cases. Other mutations, now numbering nearly 1000, are uncommon, occurring in less than 1 percent of screened populations.⁷

The nasal model for gene transfer in cystic fibrosis

Most interest in CF amongst otolaryngologists has centred around CF sinus disease. Recent reports have claimed benefit from aggressive treatment of CF sinus disease⁸ and have also suggested that the rhinologic sequelae of CF are important in production of the eventually life-threatening pulmonary complications. Not as widely reported has been the utility of the nose and sinuses in CF as a model for pulmonary disease.⁹ While the eventual goal of CF gene therapy will clearly be intrapulmonary administration, there are clearly some difficulties with the lungs for routine experimentation.

Chief amongst these concerns is safety. The prospect of an adverse reaction to vector administration in the lungs of a patient with pre-existing pulmonary compromise is

real. In a dose-escalating trial reported by Crystal *et al.*¹⁰ in 1994 of intrapulmonary adenoviral vector administration, the patient who received the largest dose developed a significant adverse reaction with opacities on chest x-ray. The risk of a significant adverse reaction in a localized area of the nose or sinuses is clearly less.¹¹ The lungs are also more inaccessible than the nose and the nose and sinuses offer ease of access for vector administration and experimental manipulation. For a variety of reasons, CF clinical trials are performed on adults. These patients invariably have severe pre-existing pulmonary compromise and any incremental benefits in pulmonary function afforded by gene therapy would be difficult to measure.

The nasal potential in CF provides a measurable endpoint for gene transfer experimentation. Nasal mucosa maintains and generates a potential difference across its surface and a characteristic voltage trace can be obtained in normal patients. In CF, the nasal mucosa, like the lung mucosa, exhibits the characteristic chloride transport abnormality. CF patients, because of their abnormal ion transport, produce a nasal potential that is different from normal both in its absolute negativity and in its response to certain pharmacologic influences.¹² This trace is so characteristic for CF that it is referred to as its bio-electric phenotype. This potential can be readily and reproducibly measured, in contrast to a number of bronchopulmonary indices and has been a target of gene therapy strategies in the nose.

In vitro and animal studies

Initially, the feasibility of gene transfer to airway cells was demonstrated *in vitro* and then in a variety of animal experiments. Only one year after the identification of the gene, Rich *et al.*¹³ showed that expression of cDNA for wildtype CFTR corrected the Cl^- channel defect in cultured CF airway epithelia. Zabner *et al.*¹⁴ demonstrated that recombinant adenoviral vectors could deliver CFTR cDNA safely in both cotton rats and rhesus monkeys. Transgenic CF mice provided a means to perform functional testing of CFTR gene expression and have even allowed reversal of the CF phenotype by gene therapy *in utero*.¹⁵ Unfortunately, however, the mice do not produce a disease state comparable to the effects of CF on human lungs.¹⁶ Encouraging *in vitro* and animal studies were the basis for progression to trials to address questions that could only be answered in humans.

Human adenovirus studies – viral vectors

Most of the early human cystic fibrosis gene therapy trials in the United States employed adenoviral vectors. Adenovirus has a degree of tropism for respiratory mucosa and a substantial body of knowledge already existed about adenoviruses as respiratory pathogens.

Recombinant viruses are produced by replacing the DNA sequence responsible for replication with CFTR cDNA. The viruses are thus replication-deficient, but still remain sufficiently active to transport genetic material into the target cell. In 1993, Zabner *et al.*¹⁷ reported correction of the CF bioelectric potential in a single-dose study where an escalating dose of vector encoding CFTR was applied to the nasal epithelium of three CF patients. Two CF patients underwent a sham procedure using saline and served as controls. No change was noted in the bioelectric phenotype in these two patients. One year later Crystal *et al.*¹⁰ published a study in which an adenovirus containing CFTR cDNA was applied to both the upper and lower respiratory tracts of four patients. No statement was made about the nasal potential, but CFTR was detected by immunohistochemistry. This report was notable for the widely publicized event of pulmonary toxicity in one of the participants following vector delivery to the lungs. This toxicity was thought to be due to vector-induced inflammation and a reduction of viral vector dose has largely overcome the problem of acute inflammation in subsequent studies. Hay *et al.*¹⁸ produced a further study revealing improvement in the nasal potential in a single escalating-dose protocol the following year.

Knowles *et al.*¹⁹ found molecular evidence of low efficiency gene transfer, but no correction of the nasal potential in a 1995 report. Their experiment involved administration of logarithmically increasing vector doses to four cohorts of three patients. A further study by Zabner *et al.*²⁰ in 1996 addressed the likely need for repeat vector administration. Six patients in two centers in the United States received four or five applications of sequentially escalating concentrations of recombinant adenovirus encoding CFTR. In this series, the correction of the nasal potential was more subtle and, importantly, evidence of immunologic response to repeat administration was noted.

Studies involving intrapulmonary vector administration have scarcely fared better. Zuckerman *et al.*²¹ delivered adenovirus encoding CFTR to a segmental bronchus in a dose-escalating study. There was evidence of low level gene expression, as well as evidence of immune and inflammatory responses. In contrast, a single-escalating dose trial from France revealed gene transfer and no detectable immune or inflammatory response after administration of Ad/CFTR.²²

Adenovirus vectors, while efficient delivery vehicles in the laboratory setting, clearly have difficulties in human trials. The human respiratory tract has evolved to efficiently repel a variety of microbial attacks, including of course adenoviruses. Adenovirus does not integrate into the genome and thus repeat administration is required. With repeat administration come concerns of inflammation and immunogenicity. All viral vectors aimed at the epithelial surface suffer from the limitation of the viral receptors being located in the basolateral membrane, away from the cell surface. This may be in

part overcome by the use of calcium chelators²³ that briefly disrupt tight epithelial functions, allowing the vector access to the basolateral membrane.

Adeno-associated virus

Serotypes 5 and 6 of the adeno-associated virus (AAV) enter airway cells from the apical surface.¹⁶ Furthermore, adeno-associated viruses offer the potential for integration into the host genome. In practical terms, however, adeno-associated viruses are also associated with inefficient expression. Using the maxillary sinus model, ten CF patients who had undergone prior maxillary antrostomy had AAV vector encoding CFTR applied to their maxillary sinus.²⁴ Molecular evidence of gene transfer was detected as late as 41 days. A functional endpoint of maxillary sinus voltage measurement was also employed. Some evidence of functional improvement was detected at day 14. There appeared to be no effect on maxillary sinusitis, as assessed endoscopically. Importantly, the utility of this model has been called into question by other studies.²⁵

Lentivirus

Lentiviruses are an apparently attractive addition to the list of possible vectors. They have the ability to integrate into and consequently persist in the host genome. They can transduce nondividing cells – an advantage in airway epithelium where cell turnover is generally low. While a variety of lentiviral options exists, most work has been carried out with the feline immunodeficiency virus (FIV).¹⁶

Nonviral vectors

The shortcomings of viral vectors have led to the investigation of nonviral delivery systems. These have included purified or naked DNA in plasmid form or ballistic gene delivery, the so-called gene gun. Only exposed surfaces accessible to a microcarrier coated with DNA are candidates for the gene gun. Most interest in nonviral gene delivery has centred on liposomes. Liposomes bind to DNA, spontaneously forming complexes that have high affinity for plasma cell membranes. DNA containing liposomes are incorporated into the cell by endocytosis. The advantages of nonviral vectors mainly revolve around safety. They are nonimmunogenic and there is no potential for insertional mutagenesis. The main difficulties with nonviral vectors relate to inefficient gene transfer and transient expression.

A 20 percent correction of nasal potential in nine patients, peaking at three days and disappearing by seven days, was reported by Caplen *et al.*²⁶ employing a cationic liposome vector. The vector was applied by a nasal pump

spray, a practical method for likely repeat administration should clinical gene therapy become a reality. In 1997, Gill *et al.*²⁷ showed functional CFTR gene transfer in six of eight subjects in a further nasal mucosal/liposome study. Alton *et al.*²⁸ reported a placebo-controlled study of liposome-mediated CFTR transfer to the lungs and nasal mucosa of CF patients. The treatment group displayed some improvement in airway potential not seen in the liposome-only group. Interestingly, some aspects of toxicity were only seen with pulmonary administration leading the authors to question the value of the nasal model, at least from a safety viewpoint.

KEY POINTS

- Remarkable progress has been made in understanding the molecular basis of cystic fibrosis.
- Equally dramatic progress has been made in examining the basic science of vector production and vector interaction with airway cells.
- The challenge remains to apply this new knowledge and *in vitro* gene therapy success to a clinically relevant and measurable endpoint.

HEAD AND NECK CANCER

In 2000, an estimated 130,000 cases of new head and neck cancer were diagnosed in developed countries.²⁹ Advances in surgical techniques, radiation treatment strategies and chemotherapy medications have improved the survival and quality of life for many of these patients. Unfortunately, despite these innovations, treatment strategies for advanced stage cancer squamous cancer and certain other head and neck cancer subtypes have not increased survival over the last 40 years.^{30, 31} In order to offer therapy in these advanced cases and to potentially augment current successful therapies, alternative treatment strategies have been examined. Many of these therapies have evolved as a result of our appreciation of the biological basis of oncogenesis. Specifically, this increased understanding has given us gene targets to potentially correct by either replacing or blocking the effect of the mutated gene. The various strategies used in gene therapy fall into four major categories: immune modulation, restorative gene replacement, selective oncolysis and chemosensitization. To accomplish these strategies, it is now possible to deliver genes by several different vectors. The following discussion will review both the methods to deliver the genes and the various strategies used with these vectors.

Delivery

The common goal of all gene therapy is to achieve expression of the gene of interest in the targeted cancer cell. To accomplish this goal several barriers must be overcome: (1) **targeting** – ideally only cells which require the gene would be affected; (2) **binding and internalization** – once a gene reaches the cells it must bind and become internalized; (3) **cellular trafficking to the nucleus** – most methods of internalization require the gene to escape from endosomal degradation and traffic through the cell to the nucleus; and (4) **nuclear expression** – once in the nucleus the quantity of gene expression and stability of expression for a given strategy also need to be determined. Each method of delivering a gene to a cell varies in its ability to overcome these barriers.

Plasmid DNA

Naked DNA is one of the most extensively studied methods of gene therapy. This nonviral method of gene therapy has several advantages. These include simplicity, ease of large scale production, minimal immune response and safety.³² The major obstacle for plasmid gene therapy is efficiency. When DNA is placed in an organism, most of the DNA is not internalized. Even if internalization does occur, endosomal degradation destroys nearly all of the remaining plasmid prior to nuclear membrane transit and expression of the desired gene does not occur. In addition, since plasmid uptake is not receptor-mediated, targeting of the plasmid to a specific cell also remains a major obstacle. In the past 15 years, substantial progress has been made in overcoming these obstacles to nonviral gene transfer.

Rapid degradation by serum nuclei and the mononuclear cell system occurs when naked DNA is injected systemically (e.g. intravascularly).³² Several strategies have been designed to overcome this barrier.^{33, 34, 35} If expression is only needed at a specific site, a gene gun, hydrodynamic injection, ultrasound, electroporation and blood flow restriction have shown promise.^{36, 37, 38, 39} Electroporation has been shown to increase interleukin (IL)-12 and interferon (IFN)-alpha expression intratumorally.^{40, 41} It may be possible to accomplish this increased electroporation by using an electrode attached to a syringe needle.⁴² If more than local expression is needed, significant advances have also been made in systemic delivery. Complexing DNA with lipids, peptides, polymers or various cationic compounds has been shown to greatly increase expression. These complexes can help with almost every component of plasmid delivery.^{43, 44} Cationic lipids and dendrimers have been shown to increase expression by increasing cell binding/internalization and decreasing endosomal degradation.^{45, 46} Targeting a specific cell type has also been shown to be possible by linking a ligand to these DNA complexes.⁴⁷

Lastly, plasmid-mediated transfer results in transient expression because the plasmid is lost with cell division. Several methods using site-specific integration or expression of viral proteins have shown promise as a means to overcome this difficulty.^{48, 49} Many of the past therapeutic attempts to utilize plasmid-mediated gene transfer have shown only modest potential. However, as all aspects of plasmid efficiency increase, this should directly correlate with the ability to utilize this technology in therapeutic interventions.

Adenovirus

Adenovirus is a human pathogenic, nonencapsulated, DNA virus. It has been extensively studied both as a means to deliver a gene both *in vitro* and in human trials. Adenovirus has several characteristics which make it suitable as a therapeutic vector in gene therapy. Relatively simple amplification methods have been developed to propagate high titer replication defective vectors.⁵⁰ Adenovirus efficiently infects both dividing and non-dividing cells by binding to the cox-adenovirus receptor.⁵¹ Once a cell binds the viral vector, adenovirus is internalized, escapes from the endosome and is trafficked to the nucleus very efficiently. Even if a specific cell is lacking viral receptors, the virus can be combined with complexes to be internalized via nonreceptor-mediated mechanisms. In this alternative pathway of entry, the other components of viral gene delivery remain intact, and therefore efficiency is maintained.^{52, 53} This relative versatility, the ease of construction, efficiency of infection and the efficient expression of transgene make adenovirus an attractive vector for gene therapy.

Adenovirus does have some drawbacks compared to other vectors and nonviral systems. It is immunogenic which limits its ability to reinfect.⁵⁴ Multiple studies have shown that both cell- and humoral-mediated immune systems are activated after viral delivery, especially if greater than 10^{10} particles are delivered.⁵⁵ This toxicity led to the well-publicized death of a subject in a University of Pennsylvania trial.¹ Besides limiting redelivery, this immune response also results in the clearance of cells expressing the transgene.⁵⁶ Several strategies have shown promise in overcoming this immune-stimulatory problem. 'Gutted' vectors, missing almost all of the viral genes, have been shown to be less immunogenic and are expressed for longer periods *in vivo*.^{57, 58} Immune modulation at the time of delivery may decrease the initial inflammatory reaction to the virus.^{57, 58} A further difficulty of adenovirus is that gene expression is transient. The viral genome does not integrate or persist with cell division and gene expression is lost as the cells divide. As demonstrated by over 50 current open protocols, the adenoviral vector is a very versatile means of gene delivery. As the obstacle of immune stimulation and persistence are addressed, this vector should only become more useful.

Retrovirus

Retroviral vectors have the substantial advantage of persistent gene expression. A discussion of retroviral vectors requires a basic understanding of the viral genome and replication. Retroviruses are small, encapsulating vectors with a genome composed of two identical single strands of RNA. The virus binds and is internalized into the cell via interactions between the cell membrane and viral capsule. Once internalized the RNA genome is reverse-transcribed and transported to the nucleus where it integrates as a provirus into the host chromosome. In a normal infectious process, this provirus would then produce viral proteins and RNA genomes for viral packaging. In all retroviral gene therapy vectors, the genome of the virus has been made replication-incompetent by removing the components of the viral gene required for packaging. Thus, these vectors integrated and express the desired gene but will not produce infectious particles.

Several retroviral systems for gene therapy are currently available. Murine oncogenic retroviruses have been the most extensively analyzed and used in preclinical studies.⁵⁹ Because murine retroviruses only infect dividing cells, the clinical utility of these initial retroviral vectors has been significantly limited.⁵⁹ To circumvent this obstacle, newer retroviral systems have been developed based on the lentivirus genus of retroviruses. This group of viral vectors which contains the human immunodeficiency virus offer the advantage of infecting dividing and nondividing cells. They have shown significant promise in preclinical *in vivo* studies.⁶⁰ A further biosafety-related issue of retroviruses is that insertion of the provirus is not controlled. It is possible that insertion of the virus next to a protooncogene may lead to therapy-induced cancer. Initial evidence from the first successful therapy in patients with severe combined immune deficiency using retroviral gene replacement suggests that a minority of the patients may have developed a nontypable lymphoproliferative disorder as a result of therapy.¹ In addition to controlling insertion, chromosomal silencing of inserted genes has also been reported. In chromosomal silencing, methylation or acetylation of the promotor leads to significant downregulation of transgene expression.^{61, 62, 63} For both of these obstacles, current research has suggested potential solutions. These include controllable chromosomal insertion, chromosomal buffers and methods to controllably excise the provirus.

Adeno-associated virus

The AAV vector has more recently emerged as a vector with significant therapeutic promise. AAV is a single-stranded encapsulated virus that belongs to the group of human parvoviruses. Several features of this virus make it attractive as a potential therapeutic tool. Firstly, although it infects human cells this virus has not been associated

with a pathologic human disease. It may, therefore, be a safer alternative than other viral vectors. Secondly, because recombinant AAV vectors do not encode viral proteins, delivery of this vector results in very little immunogenicity.^{64, 65} AAV also persists and infects dividing and nondividing cells. Although the mechanisms are not fully clear, it appears that in quiescent cells AAV integrates into the host chromosome and in rapidly dividing cells it persists as an extrachromosomal episome.⁶⁶ These factors have made this vector a popular delivery vehicle for many preclinical and human trials.

Other viral vectors

Many other viruses, including herpes and vaccinia, are currently under investigation as potential means to deliver genes. As more is understood about viral biology, it may be possible to match a particular vector with the needs of a given therapy and cell type. For instance, if long-term expression is required with low immunogenicity in muscle, it would be ideal to put the gene to be delivered in AAV. In future years, the choice of a virus for a particular cancer may be as evidence based as the choice of an antibiotic for a particular bacterial infection.

Therapy strategies

Gene therapy offers a novel paradigm that leads to the destruction of tumour cells in cancer patients. To date, the approaches to target specific cancer cells fall into four basic categories: (1) chemosensitization; (2) cytokine gene transfer; (3) inactivation of protooncogene production; and (4) selective oncolytic viruses. In the discussion to follow, the rationale and specific results from preliminary gene therapy trials will be presented.

CHEMOSENSITIZATION

Selective sensitization of cancer cells using gene therapy would be an ideal way to kill cancer cells. Using this approach, the expected gene is delivered only to cancer cells and then a second therapy (e.g. radiotherapy or chemotherapy) is used to induce killing in the cells which express the transgene. The best example of this model is delivery of herpes simplex thymidine kinase (HSV-TK).^{67, 68} In this strategy, HSV-TK is delivered to cancer cells. Once expressed, this enzyme changes the prodrug gancyclovir to its toxic nucleoside analogue, which induces cell death. Using this system one would expect that 100 percent infection of the cancer cell would be required in order to be effective. In reality, a phenomenon termed the bystander effect increases the efficiency of such therapies. In the bystander effect, the infected cell spreads the expressed genes to the cells surrounding it via cell-cell contacts. Using mixing experiments, it has been shown

that because of this effect, only half of the cells need to initially express the toxic gene to have the desired affect.^{68, 69} Transfer of *p53* is another example of chemosensitization, as inclusion of this cellular gene sensitizes a cancer cell to apoptosis after treatment with either radiation therapy or chemotherapy.⁷⁰ Initial laboratory studies showed great promise for these types of therapies. Preclinical animal studies, however, showed only modest *in vivo* results.^{67, 71} Efficiency and targeting have been shown to be difficult *in vivo*. Methods to increase cancer targeting may make these strategies more amenable for human trials in the future. These strategies include redesigning the adenovirus binding site to increase cancer cell selectivity.^{72, 73}

IMMUNE MODULATION

The host immune response has been shown to play a role in cancer eradication. Immune suppression increases the risk of cancer development. In addition to generalized suppression, it has been shown that individuals with head and neck cancer lack an effective local immune response even early in the disease.⁷⁴ This immune dysfunction begins at the site of the tumour and progresses systemically with disease progression. This dysfunction occurs as a result of the normal immune system not recognizing the tumour cells. Causes of this include immunological ignorance,⁷⁵ downregulation of major histocompatibility complexes and loss of costimulatory receptor and pathways.^{76, 77} In some tumours, the cytokine stimulatory pathways (interleukin-2 (IL-2), interferon-gamma and IL-12) which normally upregulate the normal tumour immune response are depressed. One method to break this immune dysregulation is to overexpress the downregulated cytokines. The basis of the first cytokine-based trial for locoregional disease was compelling data from preclinical studies in mice.⁷⁸ A subsequent phase I trial using soluble proteins showed three complete responses and three partial responses in 10 patients.⁷⁹ All these response were transient. A subsequent phase II trial showed similar transient responses which did not correlate with dose escalation.^{80, 81, 82} However, when IL-2 is administered systemically, significant toxicity develops, including capillary leak syndrome. Gene therapy offers the ability to increase local expression and possibly improve tumour response while limiting systemic toxicity. Phase I trials using nonviral plasmids expressing IL-2 are currently under way.⁸³ Even if such single agent cytokines do not prove useful, it may be possible to deliver combinations, which activate the immune pathway in a synergistic manner. Many such costimulatory questions are currently being examined in preclinical studies.^{84, 85, 86, 87} As our understanding of tumour immunity increases, better therapies aimed at reactivating the dysfunctional immune response will develop. Gene therapy may likely play a role in the delivery of such therapies.

Gene therapy offers to increase the tumor immune response

RESTORATIVE GENE THERAPY

Restoring the function of a key cellular gene whose dysfunction has resulted in cancer progression can be a major goal of gene therapy. Several strategies to replace dysfunctional genes are currently being tested.^{88,89} The majority of these involve the disrupted apoptotic pathway found in cancer cells. The most common mutations of these genes in squamous cell cancer of the head and neck are *p53* and *p16*. The most extensively studied of these genes in head and neck cancer is *p53*. This gene plays a role in triggering cell death in many different pathways involving apoptosis. Using an adenoviral vector, placed intralesionally, this mutated gene was delivered to 33 patients with locally recurrent squamous cell cancer in a phase I trial.⁹⁰ The study had two arms, surgical and nonsurgical. In the surgical arm, patients received treatment preoperatively, intraoperatively and postoperatively. Of these patients, four patients were alive and disease free at one year, nine died of their disease and two died of unrelated causes. In the nonsurgical arm, two of 17 had a partial response, six had stable disease and nine had progressive disease. The responses seen were most likely not due to effective replacement of mutated genes because *p53* status did not correlate with response.⁹⁰ Phase II trials with adenovirus expressing *p53* are currently being completed, as well as studies which combine this therapy with chemotherapy.⁹¹ The safety of replacing another gene, *p16*, is also currently being investigated.

SELECTIVE ONCOLYTIC VIRUS

Infection with wildtype adenovirus results in viral replication and eventual cell lysis. A therapy which harnesses this virus by only allowing replication in cancer cells would offer a self-propagating therapy which continues to produce virus and lyse cancer cells until a tumour is completely destroyed. Using replication-selective viruses to treat cancer is not entirely new. Initial reports as early as 1912 have used this approach in cancer therapy.⁹² With the advent of increased knowledge of the genetic defects in cancer, we have been able to design vectors aimed at only replicating in cancer cells.^{93,94} The ONYX-015 is an adenovirus therapy design to accomplish this goal. ONYX-015 is missing the adenovirus E1B gene which normally inhibits the cellular *p53* genes. *p53* cellular expression allows only minimal viral expression. Approximately 60 percent of squamous cell carcinoma (SCCA) do not express functional *p53*. The ONYX-015 virus will selectively replicate only in SCCA cancers with *p53* mutations. Phase I and II clinical trials have shown significant promise with this strategy.^{95,96,97} The initial phase I trial showed the virus was safe even when given in high doses.⁹⁸ Fever and injection site pain were the most common adverse effects. Phase II and III clinical trials are currently enrolling patients. In addition to developing

this therapy as a single agent treatment, its role in combined therapies is also being examined. Phase II studies have shown this combined approach increases response rates from 33 percent for chemotherapy (5-fluorouracil (5-FU) and cisplatin) to a 65 percent response rate when intratumoural injections of ONYX-015 are added to the regimen.⁹⁷ Another potential advantage of the ONYX-015 vector is that if it is given intravenously it may circulate and offer potential therapy for distant metastasis. The safety of an intravenous delivery approach has been confirmed in phase I trials revealing safe delivery of high titers of viral vectors. The most common side effects were fever, rigors and elevated liver enzymes.⁹⁶ To more fully evaluate the potential of this strategy, more work has to be completed in areas of safety and delivery. Overall, however, this self-propagating tumour selective approach offers significant therapeutic promise.

KEY POINTS

- Our increased understanding of cellular oncogenesis will lead to the development of novel cancer therapies in the years to come.
- Gene therapy is likely to be a part of these therapies.
- A head and neck oncologist will need to understand both the viral vectors and their strategies of implementation to offer a full range of treatment to the cancer patient.

Deficiencies in current knowledge and areas for future research

The death of an 18-year-old man in a 1999 adenoviral gene therapy trial in Philadelphia caused scientists around the world to examine more critically the risks of human gene therapy experimentation. Three years later, a three-year-old boy died in France from a leukaemia-like condition, probably a result of insertional mutagenesis in a retroviral gene therapy trial for SCID. Both of these tragic events have resulted in increased scrutiny for human gene therapy trials. These events have also brought into sharper focus the balance between risks and the incredible promise of this treatment. Remarkable progress has been made in the last decade in improving the understanding of the basic science and the complexities of host-vector interaction. The challenge for the next decade is to translate this new expertise into clinical situations in a safe and effective manner.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words chemotherapy and head and neck neoplasms, and focus on mechanisms of action of current and experimental drugs.

INTRODUCTION

The discovery of the toxic action of nitrogen mustards on cells of the haematopoietic system more than 50 years ago initially triggered research into the development of cytotoxic agents. The initial promise of these drugs in the management of haematological and other rare malignancies has not been sustained and cure of the more common epithelial malignancies when metastatic, remains an elusive goal.

Many of the current chemotherapeutic agents have been discovered as a result of screening compounds for cytotoxic potency *in vitro* against murine and/or human cancer cells or *in vivo* against rodent tumour models. With our better understanding of the molecular basis of cancer there is now interest in target-directed drug therapies. The aim being to develop agents that can modulate or inhibit specific molecular targets identified as being essential for tumour growth.

PRINCIPLES OF CHEMOTHERAPY

Many forms of chemotherapy are targeted at the process of cell division. The rationale being that cancer cells are more likely to be replicating than normal cells. Unfortunately as their action is not specific, they are associated with significant toxicity. An understanding of the principles of tumour biology and cellular kinetics is helpful to appreciate the mechanisms of action of cancer chemotherapy.

PRINCIPLES OF TUMOUR BIOLOGY

Cellular kinetics

CELL CYCLE

Uncontrolled cell division is a result of interference in the normal balance of the cell cycle. The cell cycle is divided into a number of phases governed by an elaborate set of

molecular switches (**Figure 4.1**). Normal nondividing cells are in G₀. When actively recruited into the cell cycle they then pass through four phases:

1. **G₁**: the growth phase in which the cell increases in size and prepares to copy its DNA;
2. **S (synthesis)**: which allows doubling of the chromosomal material;

3. **G₂**: a further growth phase before cell division;
4. **M (mitosis)**: where the chromosomes separate and the cell divides.

At the end of a cycle the daughter cells can either continue through the cycle, leave and enter the resting phase (G₀) or become terminally differentiated.

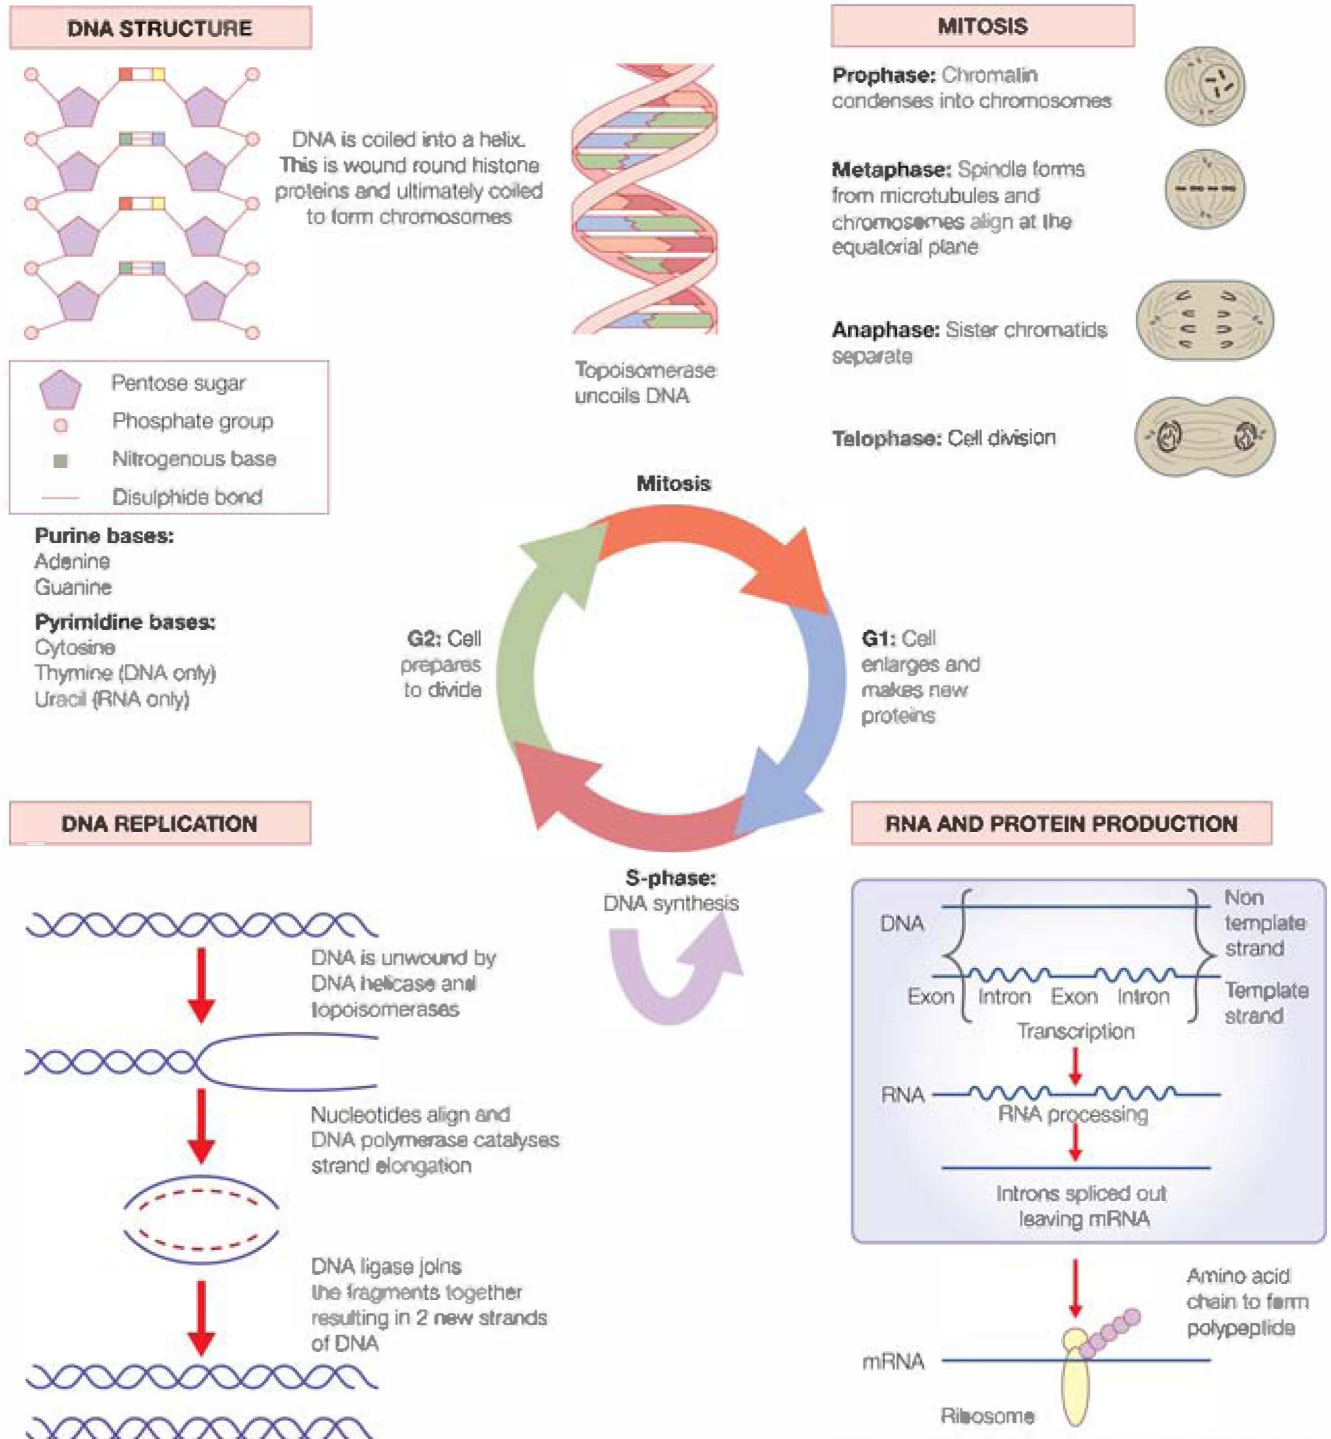

Figure 4.1 Cell cycle: possible targets for chemotherapy.

TUMOUR GROWTH

The kinetics of any population of tumour cells is regulated by the following:

- **doubling time:** the cell cycle time, which varies considerably between tissue types;
- **growth fraction:** the percentage of cells passing through the cell cycle at a given point in time which is greatest in the early stages;
- **cell loss:** which can result from unsuccessful division, death, desquamation, metastasis and migration.

Tumours characteristically follow a sigmoid-shaped growth curve, in which tumour doubling size varies with tumour size. Tumours grow most rapidly at small volumes. As they become larger, growth is influenced by the rate of cell death and the availability of blood supply.

Cell signalling

Cells respond to their environment via external signals called growth factors. These interact with cell surface receptors that activate an internal signalling cascade. This ultimately acts at the DNA level through transcription factors that bind to the promoter regions of relevant genes, stimulating the cell cycle and influencing many important processes including cell division, migration, programmed cell death (apoptosis).

ONCOGENES

Protooncogenes are involved in controlling normal cell growth. Mutated forms, known as oncogenes, can lead to inappropriate stimulation of the cell cycle and excessive cell growth. Alternatively, malignancy can also arise secondary to abnormal activation of a normal gene. The consequences of gene activation associated with tumour growth include:

- excess growth factor production;
- alteration of growth factor receptor genes so that they are permanently switched on;
- alteration of the intracellular cascade stimulating proliferation.

TUMOUR SUPPRESSOR GENES

These act as a natural brake on cell growth. Usually both alleles need to be lost for their function to be affected. This can have several important effects, which include:

- impairment of the inhibitory signals influencing receptor genes or intracellular signalling;
- loss of the counter signals controlling protooncogene function;
- inhibition of apoptosis, often as a consequence of a mutation of p53, the protein associated with DNA repair.

Metastatic spread

A tumour is considered malignant when it has the capacity to spread beyond its original site and invade surrounding tissue. Normally cells are anchored to the extracellular matrix by cell adhesion molecules, including the integrins. Abnormalities of the factors maintaining tissue integrity will allow local invasion and ultimately metastases of the tumour cells.

Mechanism of cell death

There are two main types of cell death: apoptosis and necrosis. Necrotic cell death is caused by gross cell injury and results in the death of groups of cells within a tissue. Apoptosis is a regulated form of cell death that may be induced or is preprogrammed into the cell (e.g. during development) and is characterized by specific DNA changes and no accompanying inflammatory response. It can be triggered if mistakes in DNA replication are identified. Loss of this protective mechanism would allow mutant cells to continue to divide and grow, thereby conserving mutations in subsequent cell divisions.

Many cytotoxic anticancer drugs and radiotherapy act by inducing mutations in cancer cells which are not sufficient to cause cell death, but which can be recognized by the cell, triggering apoptosis.

FRACTIONAL CELL KILL HYPOTHESIS AND DRUG DOSING

Theoretically the administration of successive doses of chemotherapy will result in a fixed reduction in the number of cancer cells with each cycle.¹ A gap between cycles is necessary to allow normal tissue recover. Unfortunately, these first-order dynamics are not observed in clinical practice. Factors such as variation in tumour sensitivity and effective drug delivery with each course result in an unpredictable cell response.

Clinical responses to antitumour therapies are defined by arbitrary criteria that have been used as part of the evaluation process in assessing the potential utility of novel agents.

- **Tumour size:**
 - complete response is defined as the apparent disappearance of the tumour;
 - partial response represents a reduction of more than 50 percent;
 - progression is defined as an increase in tumour size by more than 25 percent;
 - stable disease is an intermediate between partial response and tumour progression.
- **Tumour products:**
 - biochemical or other tests can be used to assess response, including circulating tumour markers.

CLASSIFICATION OF CHEMOTHERAPEUTIC AGENTS

Classification according to phase-specific toxicity

Cytotoxic drugs can be classified according to whether they are more likely to target cells in a particular phase of their growth cycle. More crudely, they can also be divided into whether they are more toxic to cells that are actively dividing rather than cells in both the proliferating and resting phases.

PHASE-SPECIFIC CHEMOTHERAPY

These drugs, such as methotrexate and vinca alkaloids, kill proliferating cells only during a specific part or parts of the cell cycle. Antimetabolites, such as methotrexate, are more active against S-phase cells (inhibiting DNA synthesis) whereas vinca alkaloids are more M-phase specific (inhibiting spindle formation and alignment of chromosomes).

Attempts have been made to time drug administration in such a way that the cells are synchronized into a phase of the cell cycle that renders them especially sensitive to the cytotoxic agent. For example, vinblastine can arrest cells in mitosis. These synchronized cells enter the S-phase together and can be killed by a phase-specific agent, such as cytosine arabinoside. Most current drug schedules, however, have not been devised on the basis of cell kinetics.

CELL CYCLE-SPECIFIC CHEMOTHERAPY

Most chemotherapy agents are cell cycle-specific, meaning that they act predominantly on cells that are actively dividing. They have a dose-related plateau in their cell killing ability because only a subset of proliferating cells remain fully sensitive to drug-induced cytotoxicity at any one time. The way to increase cell kill is therefore to increase the duration of exposure rather than increasing the drug dose.

CELL CYCLE-NONSPECIFIC CHEMOTHERAPY

These drugs, for example alkylating agents and platinum derivatives, have an equal effect on tumour and normal cells whether they are in the proliferating or resting phase. They have a linear dose-response curve; that is, the greater the dose of the drug, the greater the fractional cell kill.

Classification according to mechanism

Classifying cytotoxic drugs according to their mechanism of action is the preferred system in use between clinicians.

ALKYLATING AGENTS

These highly reactive compounds produce their effects by covalently linking an alkyl group ($R-CH_2$) to a chemical species in nucleic acids or proteins. The site at which the cross-links are formed and the number of cross-links formed is drug specific. Most alkylating agents are bipolar, i.e. they contain two groups capable of reacting with DNA. They can thus form bridges between a single strand or two separate strands of DNA, interfering with the action of the enzymes involved in DNA replication. The cell then either dies or is physically unable to divide or triggers apoptosis. The damage is most serious during the S-phase, as the cell has less time to remove the damaged fragments. Examples include:

- nitrogen mustards (e.g. melphalan and chlorambucil);
- oxazaphosphorenes (e.g. cyclophosphamide, ifosfamide);
- alkyl alkane sulphonates (busulphan);
- nitrosureas (e.g. carmustine (BCNU), lomustine (CCNU));
- tetrazines (e.g. dacarbazine, mitozolomide and temozolomide);
- aziridines (thiopeta, mitomycin C);
- procarbazine.

HEAVY METALS

Platinum agents

These include carboplatin, cisplatin and oxaliplatin. Cisplatin is an organic heavy metal complex. Chloride ions are lost from the molecule after it diffuses into a cell allowing the compound to cross-link with the DNA strands, mostly to guanine groups. This causes intra- and interstrand DNA cross-links, resulting in inhibition of DNA, RNA and protein synthesis.

Carboplatin has the same platinum moiety as cisplatin, but is bonded to an organic carboxylate group. This leads to increased water solubility and slower hydrolysis that has an influence on its toxicity profile. It is less nephrotoxic and neurotoxic, but causes more marked myelosuppression.

Oxaliplatin belongs to a new class of platinum agent. It contains a platinum atom complexed with oxalate and a bulky diaminocyclohexane (DACH) group. It forms reactive platinum complexes that are believed to inhibit DNA synthesis by forming interstrand and intra-strand cross-linking of DNA molecules. Oxaliplatin is not generally cross-resistant to cisplatin or carboplatin, possibly due to the DACH group.

ANTIMETABOLITES

Antimetabolites are compounds that bear a structural similarity to naturally occurring substances such as vitamins, nucleosides or amino acids. They compete with

the natural substrate for the active site on an essential enzyme or receptor. Some are incorporated directly into DNA or RNA. Most are phase-specific, acting during the S-phase of the cell cycle. Their efficacy is usually greater over a prolonged period of time, so they are usually given continuously. There are **three main classes**.

Folic acid antagonists

Methotrexate competitively inhibits dihydrofolate reductase, which is responsible for the formation of tetrahydrofolate from dihydrofolate. This is essential for the generation of a variety of coenzymes that are involved in the synthesis of purines, thymidylate, methionine and glycine. A critical influence on cell division also appears to be inhibition of the production of thymidine monophosphate, which is essential for DNA and RNA synthesis. The block in activity of dihydrofolate reductase can be bypassed by supplying an intermediary metabolite, most commonly folinic acid. This is converted to tetrahydrofolate that is required for thymidylate synthetase function (Figure 4.2).

Pyrimidine analogues

These drugs resemble pyrimidine molecules and work by either inhibiting the synthesis of nucleic acids (e.g. fluorouracil (Figure 4.3)), inhibiting enzymes involved in DNA synthesis (e.g. cytarabine, which inhibits DNA polymerase) or by becoming incorporated into DNA (e.g. gemcitabine), interfering with DNA synthesis and resulting in cell death.

Purine analogues

These are analogues of the natural purine bases and nucleotides. 6-Mercaptopurine (6MP) and thioguanine are derivatives of adenine and guanine, respectively. A

sulphur group replaces the keto group on carbon-6 in these compounds. In many cases, the drugs require initial activation. They are then able to **inhibit nucleotide biosynthesis by direct incorporation into DNA**.

CYTOTOXIC ANTIBIOTICS

Most antitumour antibiotics have been **produced from bacterial and fungal cultures** (often *Streptomyces* species). They affect the function and synthesis of nucleic acids in different ways.

- **Anthracyclines** (e.g. doxorubicin, daunorubicin, epirubicin) intercalate with DNA and affect the topoisomerase II enzyme. This DNA gyrase splits the DNA helix and reconnects it to overcome the torsional forces that would interfere with replication. The anthracyclines stabilize the DNA topoisomerase II complex and thus prevent reconnection of the strands.
- **Actinomycin D** intercalates between guanine and cytosine base pairs. This interferes with the transcription of DNA at high doses. At low doses DNA-directed RNA synthesis is blocked.
- **Bleomycin** consists of a mixture of glycopeptides that cause DNA fragmentation.
- **Mitomycin C** inhibits DNA synthesis by cross-linking DNA, acting like an alkylating agent.

SPINDLE POISONS

Vinca alkaloids

The two prominent agents in this group are vincristine and vinblastine that are extracted from the periwinkle

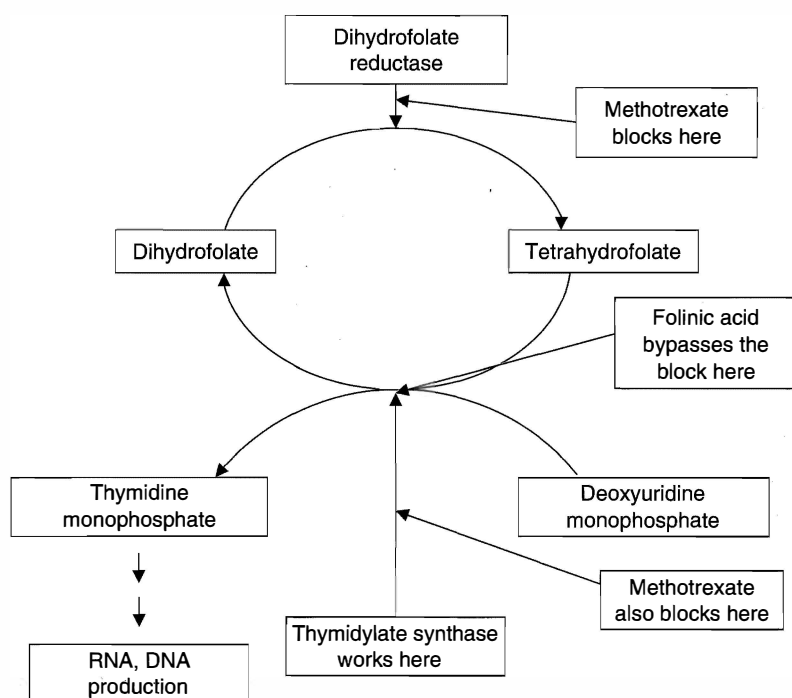

Figure 4.2 Mechanism of action of cytotoxic drugs: methotrexate.

Figure 4.3 Mechanism of action of cytotoxic drugs: Fluorouracil. 5-Fluorouracil (5FU) can participate in many reactions in which uracil would normally be involved. Firstly, it has to be converted to its active form, 5-fluoro-2 deoxyuridine monophosphate (5-FdUMP) (a). This then interferes with DNA synthesis by binding to the enzyme thymidylate synthetase, causing it to be inactivated (b). The binding can be stabilized by the addition of folinic acid. 5FdUMP, 5-fluorodeoxyuridine monophosphate; 5FU, 5-fluorouracil; 5FUMP, 5-fluorouridine monophosphate; dTMP, deoxythymidine monophosphate; dUMP, deoxyuridine monophosphate; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate; PP, pyrophosphate; PRPP, 5-phospho- α -D-ribose 1-diphosphate; U, uracil; UMP, uridine monophosphate.

plant. They are mitotic spindle poisons that act by binding to tubulin, the building block of the microtubules. This inhibits further assembly of the spindle during metaphase, thus inhibiting mitosis. Although microtubules are important in other cell functions (hormone secretion, axonal transport and cell motility), it is likely that the influence of this group of drugs on DNA repair contributes most significantly to their toxicity. Other newer examples include vindesine and vinorelbine.

Taxoids

Paclitaxel (Taxol) is a drug derived from the bark of the pacific yew, *Taxus brevifolia*. It promotes assembly of microtubules and inhibits their disassembly. Direct activation of apoptotic pathways has also been suggested to be critical to the cytotoxicity of this drug.² Docetaxel (Taxotere) is a semisynthetic derivative.

TOPOISOMERASE INHIBITORS

Topoisomerases are responsible for altering the 3D structure of DNA by a cleaving/unwinding/rejoining

reaction. They are involved in DNA replication, chromatid segregation and transcription. It has previously been considered that the efficacy of topoisomerase inhibitors in the treatment of cancer was based solely on their ability to inhibit DNA replication. It has now been suggested that drug efficacy may also depend on the simultaneous manipulation of other cellular pathways within tumour cells.³ The drugs are phase-specific and prevent cells from entering mitosis from G2. There are two broad classes:

Topoisomerase I inhibitors

Camptothecin, derived from *Camptotheca acuminata* (a Chinese tree), binds to the enzyme–DNA complex, stabilizing it and preventing DNA replication. Irinotecan and topotecan have been derived from this prototype.

Topoisomerase II inhibitors

Epipodophyllotoxin derivatives (e.g. etoposide, vespide) are semisynthetic derivatives of *Podophyllum peltatum*, the American mandrake. They stabilize the complex between

topoisomerase II and DNA that causes strand breaks and ultimately inhibits DNA replication.

LIMITATIONS OF CYTOTOXIC AGENTS

There are a number of problems with the safety profile and efficacy of chemotherapeutic agents. Cytotoxics predominantly affect rapidly dividing cells so do not specifically target cancer cells in the resting phase. They also only influence a cell's ability to divide and have little effect on other aspects of tumour progression such as tissue invasion, metastases or progressive loss of differentiation. Finally, cytotoxics are associated with a high incidence of adverse effects. The most notable examples include bone marrow suppression, alopecia, mucositis, nausea and vomiting.

CHEMOTHERAPY IN HEAD AND NECK CANCER

Worldwide, squamous cell cancer of the head and neck accounts for an estimated 500,000 new cancer cases per year. One-third of these patients present with early stage disease that is amenable to cure with surgery or radiotherapy alone. The remaining patients usually present with locally advanced disease. Unfortunately, this group exhibit high recurrence rates of approximately 65 percent despite radical surgery and radiotherapy. To date, the addition of chemotherapy has not changed this. It has, however, allowed improved organ preservation when combined with radiotherapy and has led to a reduction in rates of distant metastases. Chemotherapy also has a role in the palliative treatment of advanced disease.

Currently, surgery or radiotherapy are the standard curative options for early stage head and neck cancer. Chemotherapy in combination with surgery, radiotherapy or both is employed for locoregionally advanced disease. Stage IV disease is managed with palliative chemotherapy (see also Chapter 200, Developments in radiotherapy for head and neck cancer).

CHOICE OF CHEMOTHERAPY IN HEAD AND NECK CANCER

The single agents active in head and neck cancer, with response rates between 15 and 40 percent, include methotrexate, cisplatin, carboplatin, fluorouracil, ifosfamide, bleomycin, paclitaxel and docetaxel. Cisplatin is particularly popular for use either as a single agent or in combination with other drugs because for a long time it was viewed as one of the most active drugs in squamous head and neck cancer.⁴ Taxoids and gemcitabine are now gaining favour and are being incorporated into many current drug trials. [***]

CHEMOTHERAPY STRATEGIES

Combination chemotherapy

Combinations of cytotoxic agents are widely used for many cancers and may be more effective than single agents. Possible explanations for this include:

- exposure to agents with different mechanisms of action and nonoverlapping toxicities;
- reduction in the development of drug resistance;
- the ability to use combinations of drugs that may be synergistic.

In practice, the predominant dose-limiting toxicity of many cytotoxic drugs is myelosuppression and this limits the doses of individual drugs when used in combination.

Adjuvant chemotherapy

This is the use of chemotherapy in patients known to be at risk of relapse by virtue of features determined at the time of definitive local treatment (e.g. tumour grade, lymph node status, etc.). The intention of adjuvant chemotherapy is therefore the eradication of micrometastatic disease.

Randomized trials assessing the use of adjuvant chemotherapy for the patients with head and neck squamous carcinoma do not suggest a significant benefit.⁵ [****]

Neoadjuvant chemotherapy

Neoadjuvant, or induction chemotherapy, is the use of chemotherapy before definitive surgery or radiotherapy in patients with locally advanced disease. The intention of this strategy is to improve local and distant control of the disease in order to achieve greater organ preservation and overall survival.

Numerous phase III trials have considered the benefit of neoadjuvant chemotherapy followed by definitive surgery, by surgery and radiotherapy, or by radiotherapy alone as compared to definitive management without chemotherapy. Unfortunately, these studies have not demonstrated a survival advantage. To date, only subset analyses of trials using neoadjuvant cisplatin and 5-fluorouracil combination chemotherapy compared with locoregional treatment alone have shown a small survival gain.⁵ In addition, neoadjuvant chemotherapy has been shown to have little impact on reducing locoregional failure. This is perhaps surprising given the consistently observed high initial tumour response rates of up to 70–85 percent.

The role of neoadjuvant chemotherapy therefore continues to remain controversial and further studies are planned, particularly looking at more effective drug combinations. [****]

Concurrent chemoradiation

This involves the synchronous use of chemotherapy and radiotherapy. Multiple randomized trials comparing concurrent radiotherapy and chemotherapy with radiotherapy alone have shown significant improvement in locoregional control, relapse-free survival and overall survival rates in patients with locally advanced, unresectable disease.⁶ These results may reflect the influence of chemotherapy on micrometastatic disease or its ability to enhance tumour radiosensitivity.⁷ Some chemotherapy agents are recognized to be more active in certain radioresistant cell types. Other drugs may act synergistically with radiotherapy by hindering the repair of radiation-induced DNA damage (cisplatin), by synchronizing or arresting cells during radiosensitive phases (hydroxyurea, paclitaxel) or by hindering regrowth between fractions of treatment.

Many different drug combinations and radiation schedules have been evaluated. Each combination clearly has unique toxicities, risks and benefits. At present, there is still debate regarding the optimum chemoradiotherapy regimen that should become the standard of care. [****/**]

High-dose chemotherapy

Many chemotherapy drugs have a linear dose-response curve, but their use at high doses is limited by myelosuppression. This may be overcome by using bone marrow or peripheral stem cell infusions. While high-dose chemotherapy appears to have a role in the management of leukaemias, myeloma and certain lymphomas, little benefit has been demonstrated in common solid tumours. [****]

Chemoprevention

This is a novel approach with the aim of reversing or halting carcinogenesis with the use of pharmacologic or natural agents. Retinoids have been tested in head and neck carcinogenesis both in animal models and against oral premalignant lesions and in the prevention of secondary tumours in humans, with initial encouraging results.^{8,9} Studies are also looking at the benefit of using cyclo-oxygenase 2 (COX-2) inhibitors in a similar role.¹⁰ [**]

NOVEL THERAPIES FOR THE FUTURE

Despite the introduction of new cytotoxic drugs, such as antimetabolites (capecitabine) and topoisomerase I inhibitors, the management of advanced head and neck cancer remains challenging. Over the last years interest has focussed more on novel agents with a more targeted mechanisms of action.

Targeted therapy aims to specifically act on a well-defined target or biologic pathway that, when inactivated, causes regression or destruction of the malignant process. The main strategies of research have looked at the use of monoclonal antibodies or targeted small molecules.

Monoclonal antibodies

In the early 1980s, it became apparent that targeted therapy using monoclonal antibodies (MAb) might be useful in the detection and treatment of cancer. Monoclonal antibodies can be derived from a variety of sources:

- murine: mouse antibodies;
- chimeric: part mouse/part human antibodies;
- humanized: engineered to be mostly human;
- human: fully human antibodies.

Murine monoclonal antibodies may themselves induce an immune response that may limit repeated administration. Humanized and, to a lesser extent, chimeric antibodies are less immunogenic and can be given repeatedly.

There are several proposed mechanisms of action of monoclonal antibodies.¹¹ These include:

- direct effects:
 - induction of apoptosis;
 - inhibition of signalling through the receptors needed for cell proliferation/function;
 - anti-idiotypic antibody formation, determinants amplifying an immune response to the tumour cell;
- indirect effects:
 - antibody-dependent cellular cytotoxicity (ADCC, conjugating the 'killer cell' to the tumour cell);
 - complement-mediated cellular cytotoxicity (fixation of complement leading to cytotoxicity).

A desirable target for MAbs would have the following properties:

- wide distribution on tumour cells;
- high level of expression;
- bound to tumour, allowing cell lysis;
- absent from normal tissues;
- trigger activation of complement on MAb binding;
- limited antigenic modulation of target.

Antibodies have also been used as vectors for the delivery of drugs and radiopharmaceuticals to a target of tumour cells.

The earliest and most successful clinical use of antibodies in oncology has been for the treatment of haematological malignancies. Interest in the development of antibodies for solid tumours has become increasingly popular, especially with respect to the epidermal and vascular endothelial growth factor receptors.

Epidermal growth factor receptor biology

Epidermal growth factor receptor (EGFR) biology is a 170-kDa transmembrane protein composed of an extracellular ligand-binding domain, a transmembrane

lipophilic region and an intracellular protein tyrosine kinase domain (Figure 4.4). When a substrate binds to the receptor, the ligand–receptor complex dimerizes and is internalized by the host cell. This activates an intracellular protein kinase by autophosphorylation, which in

turn activates signal transduction pathways, influencing cell function. This can lead to cell proliferation, as well as invasion and metastasis.

Several investigators have described amplification of the EGFR gene and overexpression of the EGFR surface membrane protein in a large number of human cancers, including squamous cell carcinoma of the head and neck.¹²

Overexpression is associated with increased proliferative capacity and metastatic potential and is an independent indicator of poor prognosis.¹³ Blockade of the EGFR pathway has been shown to inhibit the proliferation of malignant cells and also appears to influence angiogenesis, cell motility and invasion.¹⁴ Various strategies have been investigated to manipulate EGFR.

Monoclonal antibodies against epidermal growth factor receptor

MAB technology has been directed against EGFR. The chimeric IgG antibody cetuximab (C225) has the binding affinity equal to that of the natural ligand and can effectively block the effect of epidermal growth factor and transforming growth factor α .⁶ It has been shown to enhance the antitumour effects of chemotherapy and radiotherapy in preclinical models.^{15, 16, 17} More recently, cetuximab has been evaluated alone and in combination with radiotherapy and various cytotoxic chemotherapeutic agents in a series of phase II and III studies involving patients with head and neck cancers.^{15, 18} The studies are encouraging, but it is still too early to determine the exact role the antibody will play in treatment regimens.

Targeted small molecules against epidermal growth factor receptor

Gefitinib (Iressa) and erlotinib (Tarceva) are orally active epidermal growth factor receptor tyrosine kinase inhibitors (EGFR-TKI) that block the EGFR signalling cascade, thereby inhibiting the growth, proliferation and survival of many solid tumours. They have single agent activity in patients with recurrent or metastatic head and neck cancer, and have an acceptable safety profile compared with conventional chemotherapy.^{19, 20} Results of phase III trials are awaited and will help determine their optimal use in head and neck cancers.

Interestingly, one of the noted side effects of the drugs is an acneiform rash. Analysis of phase II trials of erlotinib in nonsmall-cell lung cancer, head and neck cancer and ovarian cancer shows a significant association between the rash severity and objective tumour response and overall survival.²¹ Similar findings have been made with cetuximab and gefitinib. This association suggests that the rash may serve as a marker of response to treatment and could be used to guide treatment to obtain optimal dose.

Despite these successes, these agents have modest activity when used as single agents in unselected patients. It is clear that the clinical development of these agents is far from simple. It is important that we try to understand better the biological and clinical criteria for patient selection and also how best to use the different available agents. The recent discovery of EGFR mutations and the potential identification of other markers that might predict patient response could help to optimize the use of these agents in the future.

Inhibitors of angiogenesis

Angiogenesis is the process of new blood vessel formation, triggered by hypoxia and regulated by numerous stimulators and inhibitors (Figure 4.5). It is vital for cancer development. A tumour cannot extend beyond 2–3 mm without inducing a vascular supply. New vessels develop on the edge of the tumour and then migrate into the tumour. This process relies on degradation of the extracellular matrix surrounding the tumour by matrix metalloproteinases, such as collagenase, that are expressed at high levels in some tumour and stromal cells. Angiogenesis is then dependent on the migration and proliferation of endothelial cells.

It has been found that antiangiogenic agents tend to be cytostatic rather than cytotoxic, hence stabilizing the tumour and preventing spread. As a consequence, they may be valuable for use in combination with cytotoxic drugs, as maintenance therapy in early-stage cancers or as adjuvant treatment after definitive radiotherapy or surgery. There is evidence to support the fact that suppressing angiogenesis can maintain metastases in a state of dormancy.²² Interestingly, development of resistance does not appear to be a feature of these drugs.²³ [**]

Vascular endothelial growth factor receptor

Vascular endothelial growth factor is a multifunctional cytokine released in response to hypoxia and is an important stimulator of angiogenesis. It binds to two structurally related trans-membrane receptors present on endothelial cells, called Flt-1 and KDR. High VEGF protein and receptor expression has been demonstrated in certain head and neck cancers and is associated with a higher tumour proliferation rate and worse survival.²⁴

Monoclonal antibodies against vascular endothelial growth factor receptor

Bevacizumab (Avastin) is a humanized murine monoclonal antibody targeting VEGF. It is the first antiangiogenic drug to have induced a survival advantage in cancer therapy, within a randomized trial of irinotecan,

Pro-angiogenic factors	Anti-angiogenic factors

5-fluorouracil, leucovorin combined with bevacizumab or placebo in metastatic colorectal cancer.²⁵ The use of bevacizumab in head and neck cancer is supported by data from preclinical studies.²⁶ Currently, clinical trials are exploring the feasibility and the therapeutic potential of a combination of bevacizumab and EGFR-targeted drugs.²⁷

OTHER NOVEL TREATMENTS

There are now a large number of new types of agents entering all phases of clinical trials. To date, they have met with variable success. It is important to mention a few drugs which have really made an impact on treatment of specific cancers in the last few years.

- **Trastuzumab (Herceptin):** A humanized monoclonal antibody against the HER-2-receptor which is now becoming increasingly important in the treatment of both locally advanced and metastatic breast cancer.
- **Imatinib mesylate (Gleevec):** An adenosine triphosphate binding selective inhibitor of bcr-abl that has been shown to produce durable complete haematologic and cytogenetic remissions in early chronic phase CML. It also has remarkable activity against relapsed and metastatic gastrointestinal stromal tumours (GIST) that characteristically feature a mutation in the c-kit receptor tyrosine kinase gene.

- **Ritiximab (Mabthera):** The rituximab antibody is a genetically engineered chimeric murine/human monoclonal antibody directed against the CD20 antigen found on the surface of normal and malignant B lymphocytes. It is being increasingly used in combination with chemotherapy to manage many different types of indolent and aggressive B-cell lymphomas.
- **Bortezomib (Velcade):** Velcade is the first of a new class of agents called proteasome inhibitors and the first treatment in more than a decade to be approved for patients with multiple myeloma.

The proteasome is an enzyme complex that exists in all cells and plays an important role in degrading proteins fundamental to all cellular processes, in particular those involved in cell growth and survival. Velcade is a potent but reversible inhibitor of the proteasome. By disrupting normal cellular processes, proteasome inhibition promotes apoptosis. Cancer cells appear to be more susceptible to this effect than normal cells. Due to the reversibility of proteasome inhibition with Velcade, normal cells are more readily able to recover, whereas cancer cells are more likely to undergo apoptosis.

CONCLUSION

The majority of conventional chemotherapeutic agents cause cell death by directly inhibiting the synthesis of

DNA or interfering with its function. This means that they are often not tumour-specific and are associated with considerable morbidity. Trials have demonstrated that combination chemotherapy regimens can cause dramatic regression of head and neck tumours, especially when used concomitantly with radiotherapy. Unfortunately, this has not been associated with an increase in survival rates.

There is considerable excitement over the development of new target-directed cytotoxic agents. These have been developed to modulate or inhibit specific molecular targets critical to the development of or control of cancer cells. Particular interest has focussed on the field of monoclonal antibody development, particularly in relation to the epidermal growth factor. Other drugs affecting signal transduction, programmed cell death, transcription regulation, matrix invasion and angiogenesis are currently involved in clinical trials. The results of these are obviously eagerly awaited and will potentially radically change current therapeutic strategies.

KEY POINTS

- Traditional chemotherapy agents interfere with DNA synthesis and function and are classified according to their mechanism of action.
- Many agents are associated with significant side-effect profiles.
- The role of chemotherapy in head and neck cancer is still being defined, but there is increasing popularity of concurrent chemotherapy and radiotherapy regimens.
- Current research is focussing on molecular targeted therapy.
- Recent strategies have looked at the use of monoclonal antibodies.
- Drugs are being designed that influence signal transduction, specifically cell cycle regulation, apoptosis, matrix invasion and angiogenesis.
- Results of clinical trials are eagerly awaited.

Deficiencies in current knowledge and areas for future research

The effect of chemotherapy on nonmetastatic head and neck cancers is still being elucidated. The optimum combination of chemotherapeutic agents and the timing of their use in relation to surgery have not been defined, especially in combination with radiotherapy. As this continues to be assessed, significant advances are being

made in relation to more specific targeted therapies. The results of clinical trials with these new agents and their incorporation into management regimens are eagerly awaited.

- The optimum regimen of chemotherapy agents for use in head and neck cancers needs to be defined aiming to improve survival, quality of life and organ function.
- The role of molecular target-specific chemotherapy agents in the management of head and neck cancers needs to become more familiar.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words neoplasms, radiotherapy, radiation-sensitizing agents, drug therapy and antineoplastic agents

INTRODUCTION

Radiotherapy is the therapeutic use of ionizing radiation, usually high-energy x-rays (photons), although gamma rays, high-energy electron beams and other particle beams (hadrons) have all been employed clinically. As the name implies, the radiation interacts with matter by ejecting electrons from their orbits, resulting in ionization. The ejected particles interact with further atoms, ejecting further electrons and causing a cascade of ionizations after each initial interaction. In biological material, the free radicals that result, primarily from interactions with water molecules, are highly reactive and are particularly damaging to the cell when they interact with DNA (hydrated electrons are rapidly deactivated by oxygen, see under Bioreductive drugs). In total, about 100 distinct lesions have been identified amongst which strand breaks (i.e. sugar-phosphate backbone damage) predominate in terms of importance at the cellular level. Traditionally, the main cause of cell death following radiation was thought to result from direct damage to the DNA. This has gradually been modified over the last few years as an increasing number of studies have shown, that ionizing radiation also targets the plasma membrane where it can initiate multiple signal transduction pathways, many of which lead to radiation-induced apoptosis (e.g. hydrolysis

of the membrane phospholipid sphingomyelin by the enzyme sphingomyelinase resulting in the generation of ceramide). DNA damage in mammalian cells triggers three pathways: cell cycle arrest, DNA repair and apoptosis. Historically, three types of damage have been recognized: sublethal damage (SLD), potentially lethal damage (PLD) and irreparable or lethal damage. These categories may not reflect different types of damage, but instead reflect the category of repair processes that act to modify the radiation-induced lesions. If the DNA damage is particularly severe then cell death may result, usually when the cell attempts to divide.

The fact that cell death occurs at a time after the actual exposure to irradiation, depending on the time of cell division (and also upon the tissue structure and life span of the mature functional cells), explains one of the most important clinical observations about radiotherapy, that tissues that are dividing rapidly manifest the effects of radiation sooner than those where cell division is slow. Tissues such as bone marrow, skin and the mucosa of the upper aerodigestive tract manifest the effects of radiation within days. Connective tissue, bone and neural tissue may only show the effect years later. Squamous head and neck cancers, as might be expected, behave as an acute-reacting tissue, like the squamous mucosa from which they originate. In addition to the kinetics (turnover rate)

of the population as a whole, the response of tissues and organs is also dependent upon inherent cellular radio-sensitivity. The sensitivity of the cell to radiation is determined to some degree by its state of maturity and its functional role. Generally speaking, immature cells are considerably more sensitive to radiation than mature cells and as mitotic activity increases (metabolic activity, proliferation), sensitivity also increases. There is general agreement as to which of the target cells is responsible for acute effects (stem cells of rapidly dividing tissues), but the target cells that determine the late effects have not been defined clearly. In general, if any clonogens from acute responding normal tissues survive they can rapidly repopulate and replace lost cells. Late-reacting tissues do not have this ability to repopulate rapidly and therefore whilst most acute reactions heal, most late reactions, if anything, continue to progress with time. It is the severity of predicted late effects that can limit the delivered dose of radiation.

Hyperfractionation = more fractions of smaller each dose FRACTIONATION

The differences between 'acute-reacting' and 'late-reacting' tissues are very important to the science of fractionation in radiotherapy. At low single doses, tumour and early-responding tissues are more sensitive than late-responding tissues (more cells are in cycle). At high doses, the nondividing late responding cell response that compensates for tissue loss is slow and therefore organs appear more radiosensitive than rapidly dividing tumour and early-responding tissues.

A fraction is the individual dose of radiation delivered at a single session of radiotherapy; in the treatment of head and neck cancer a total course of radiotherapy will take several weeks and consist of numerous fractions. The fraction size, measured in physical dose, is traditionally and almost invariably constant throughout a course of radiotherapy. In conventional radiotherapy, fractions are given once a day, five days per week. This accords with normal working practices, rather than being founded on a sound scientific basis, and alternative fractionation schedules have been much studied in recent years (see below).

In general, the relationship between the dose of radiation in a single fraction and the number of cells killed approximates closely to a straight line on a semilogarithmic graph, conventionally drawing dose arithmetically on the x-axis and surviving fraction of cells on a declining logarithmic scale on the negative y-axis. This is shown in Figure 5.1. It should be noted though that while the general relationship is linear, at the lowest doses this is not so, and the line is curved (has a shoulder). For most cells, the range in which this curve applies is close to most widely used fraction sizes (in other words around 2 Gy) and this has important implications for clinical practice.

Figure 5.1 Typical radiation dose-response curve following a single radiation exposure. Note that the radiation dose (x-axis) is a linear scale, while surviving fraction (y-axis) is logarithmic. The effect for small doses is relatively 'curvy' compared to that for higher. The consequences of this are explained in the text.

The extent of the 'curviness' of the graph varies with many factors. Most importantly for day-to-day routine radiotherapy, late-reacting tissues generally have a more 'curvy' graph than do acute-reacting ones and therefore increasing the fraction size tends to have a greater effect (altered severity) on late-reacting as opposed to early-reacting tissues. Graphs for exposure to neutrons or other heavy particles tend to be less curvy than do those for x-rays. Cells from patients with ataxia-telangiectasia show almost no curve. This is because these patients are deficient in certain mechanisms that act to repair DNA. The shoulder on the graph is a reflection of the capacity for DNA to repair damaged cells.

The importance of this 'shoulder region' to radiotherapy relates to the fact that as long as sufficient time elapses between fractions, a subsequent dose of radiation has the same shaped survival curve as an initial dose, including the shoulder, i.e. full repair of the initial damage has occurred. Thus, if the shoulder is considerable, the net effect of two doses is very much less than if the same total physical dose was given as a single fraction. The general shape of the cell survival curves, including the shoulder, is probably best described by the linear quadratic equation:

$$SF = N/N_0 = e^{-(\alpha D + \beta D^2)} \quad \text{or} \quad -\ln SF = \alpha D + \beta D^2$$

In this equation, N_0 is the number of cells in the population originally and N is the number surviving after irradiation with dose D , with N/N_0 representing the surviving fraction (SF). Only two parameters, α (the initial slope) and β (the terminal slope) are required to describe the dose-response curve. Absolute values of alpha and beta are not well known, but the alpha/beta ratio (i.e. the dose at which the contribution to killing from the α component or nonreparable damage, is equal to that of the β component or reparable damage) has been identified with a reasonable degree of approximation for numerous tissues. In general, the α/β ratio tends to be

low for late-reacting tissues, and for these the shoulder on the graph is considerable, whereas it is high for acute-reacting tissues, where the shoulder is less marked. As mentioned above, when this is translated into practice, the total effect is more fraction size-dependent for late-reacting tissues than for acute-reacting tissues. Thus, for example, the effect achieved with a dose of 70 Gy in 2 Gy fractions will differ less from the effect of the same total dose in fractions of 1 Gy for acute-reacting tissues than it will be for late-reacting tissues. There will be more 'sparing' of late-reacting tissues by breaking the same total dose up into a greater number of smaller fractions. Having said this, because of the ability of early-reacting tissue (notably head and neck squamous cell carcinomas (SCC)) to repopulate rapidly, these comparisons are only valid if the overall treatment time is the same for the different schedules. This necessitates a shorter interfraction interval for the schedule of many small fractions. This interval still needs to be long enough for adequate repair of sublethal damage to occur if the full sparing effect on late reactions by reducing factor size is to be seen.

The corollary of this is that by using many small fractions it will be possible to give a higher total dose, but without increasing the amount of late damage, whereas a greater effect will be seen on acute-reacting tissues, notably squamous head and neck cancers. This is the theory of 'hyperfractionation'.

The theoretical benefits of hyperfractionation were confirmed in clinical practice in a randomized trial comparing a 'conventional' schedule of 70 Gy in seven weeks with a hyperfractionated schedule, in which two fractions of 1.15 Gy were given daily, also over seven weeks, so that the total dose was 80.5 Gy.¹ [****] Better local control was achieved in the experimental hyperfractionation arm, with no observed increase in late side effects.

Other ways of modifying radiotherapy fractionation schedules have also been explored in head and neck cancer. The problem of tumour clonogen proliferation during a prolonged course of radiotherapy has already been alluded to. The consequence of this is that if radiotherapy schedules are prolonged for reasons such as holidays, machine breakdowns and so on, tumour control is adversely affected. A number of retrospective series have confirmed this (it cannot, of course, be ethically tested in a prospective randomized trial). The evidence has been strong enough for the Royal College of Radiologists in the UK to publish guidelines on how to minimize the harm done by such interruptions.² [*] Of course, if prolongation of schedules is detrimental in terms of control of tumours, it might well be expected that to shorten the overall time (acceleration) would result in better control. A number of trials have also been set up to test this hypothesis. overall time is beneficial in terms of tumour control. One problem that all the trials of accelerated treatments have

faced is that increasing the effect on the tumour by shortening the overall time also increases the effect on the adjacent normal mucosa, and severe acute reactions are to some extent unavoidable. The problem is compounded by the fact that very severe acute reactions sometimes lead, rather more than might be expected, to an increase in the extent of late reactions, and this has rather limited the extent to which improvements in outcomes can be achieved by shortening radiotherapy schedules. Even so, the many studies published in this area leave little doubt that it is indeed possible to employ the strategy of acceleration without incurring too high a penalty in terms of normal tissue effects, although the optimum strategy in terms of fraction size, interval, number of fractions per day, number of treatment days per week, total dose and overall time, remains elusive.³

RADIOSENSITIZERS

As well as modifying the physical parameters (time, dose, etc.) of radiotherapy, other interesting avenues of exploration have involved using various agents to enhance its effects. It is reasonable to refer to all of these as 'radiosensitizers', although the scientific purists may argue about the appropriate use of this term. Numerous types of agents have been used, with varying degrees of success. The rapid advances that are currently occurring in molecular oncology seem likely to make this an area of fruitful exploration in the near future.

The evidence that emerged from laboratory studies that hypoxic cells were relatively radioresistant to x-rays when compared with fully oxygenated ones prompted the earliest attempts at radiosensitization. As the centre of many tumours are necrotic, it was felt that this was evidence that the proliferation of cells within tumours led to growth outstripping blood supply (i.e. the diffusion distance for oxygen is ~150–200 µm from an adjacent blood vessel) and that therefore it was logical to assume that there would be many chronically hypoxic cells within tumours (hypoxia can also be acute due to the transient opening and closing of tumour blood vessels). It was hypothesized that chronic and acute hypoxia would make the centre of tumours relatively radioresistant. Modern technology has made it possible to precisely measure oxygen levels in tumour and normal tissues, and this hypothesis has indeed been confirmed. If this hypoxic effect could be overcome, radiotherapy would be more likely to be successful. A significant amount of time and effort has been expended over many years testing whether this could be achieved in clinical practice. Many diverse strategies have been employed and new strategies are continually being investigated.

The earliest avenue explored was probably the most direct. In an attempt to ensure greater oxygenation within tumours, patients were placed in hyperbaric oxygen tanks during radiotherapy. Clinical trial results failed to

demonstrate that this approach yielded better results than 'standard' radiotherapy. There have been reports that increasing the haemoglobin level could be beneficial as anaemic patients may respond less well to radiotherapy.^{4,5} [***] Initial studies suggested that those patients given transfusions and hyperbaric oxygenation (HBO) did better than those given HBO alone, however, recent results with recombinant erythropoietin have not been very encouraging.⁶ [***]

An alternative approach used the agent nicotinamide, which is thought to dilate small vessels to improve blood flow through the vascularized parts of tumours, in combination with patients breathing carbogen (a mixture of oxygen and carbon dioxide) during radiotherapy in an attempt to ensure good oxygenization.⁷ Randomized phase III trials are currently underway and the results awaited. A reversal of this approach has met with limited success in certain situations, i.e. tourniquet hypoxia has been used to reduce the radiosensitivity of normal tissues in patients with osteosarcomas of limbs.

A number of pharmaceutical approaches have been used in an attempt to make hypoxic tumour cells more radiosensitive. True sensitizers have little or no cytotoxic action without radiation, but significantly enhance the efficiency of radiation killing when present during radiation. Apparent sensitizers include a variety of compounds, such as antibiotics, alkylating agents and antimetabolites, that act by diverse mechanisms. In general, sensitizers can be regarded as agents that increase the lethal effects of radiation. They should show a gain between tumours and normal tissues. Such a therapeutic gain could result from selective uptake (concentration), a differential absorption rate or biological half-life. Ideally they should be effective at systemically nontoxic dosages, thereby minimizing side effects.

Halogenated pyrimidines (IUDR, BrdUrd) work by being incorporated into actively dividing tumour cells to a greater degree than slowly dividing (cell maintenance) normal tissues. Appreciable quantities need to accumulate for several generations for them to be incorporated to set up stresses in the DNA and make them more susceptible to radiation damage. They therefore seem to be particularly useful with tumours having a high growth fraction and high labelling index. BrdUrd is also a sensitizer to ultraviolet (UV) radiation therefore skin may be the limiting tissue. This is less of a problem with IUDR.

Hypoxic cell sensitizers are electron affinic and act to increase the sensitivity of radioresistant hypoxic cells by mimicking O₂. They are not rapidly metabolized and therefore have time to diffuse into poorly vascularized areas.

Cells are more responsive to sensitizers if they are depleted of their natural radioprotector, glutathione (GSH), a radical scavenger that eliminates reactive radicals before they have the opportunity of causing DNA damage. This may be accomplished by incubation with thiol binding agents, such as diamide and

diethylmaleate, or inhibition of GSH synthesis with buthionine sulfoximine before delivering the radiation. The effectiveness of hypoxic cell sensitizers is measured in terms of the enhancement ratio (ER).

The nitroimidazoles have been extensively evaluated as potential radiosensitizers. One of the first compounds investigated was metronidazole, a trichomonacide. At 10 mM, an ER of 1.6 was obtained with no effect on aerated cells. The large concentrations required led to investigations for more effective derivatives and other nitroimidazole drugs appeared more promising in this respect.

Although many hypoxic cell sensitizers have been investigated (including misonidazole, metronidazole, benznidazole, desmethylmisonidazole, etanidazole, pimonidazole, nimorazole, ornidazole and doranidazole), controversy exists regarding the role of these agents in conventional radiotherapy. So far only one major randomized trial of the many that have been performed has shown a therapeutic benefit and in this Danish trial, a benefit for nimorazole use during radiotherapy of pharyngeal and supraglottic laryngeal cancers when combined with conventional therapy was shown.⁸ [****] Although nimorazole has been shown to be of potential benefit, these sensitizers generally show greater benefit in situations where large, single doses of radiation are given (e.g. intraoperative radiotherapy, interstitial radiotherapy, radiosurgery). As only this one trial out of many has shown a statistically significant benefit, the international clinical community remains unconvinced that there is a true benefit for the use of nitroimidazoles, and they are still not widely used outside Denmark.

BIOREDUCTIVE DRUGS

Adjuncts to radiation, which are not true radiosensitizers, include bioreductive drugs. These agents are reduced intracellularly to form cytotoxic agents. Bioreduction is favoured under hypoxic conditions (due to cytochrome P450 and DT diaphorase reductases). The efficiency of bioreductive drugs may be increased by inducing increased hypoxia in tumours through the use of vasoactive drugs, such as hydralazine. This induces vasodilation in normal tissues thus diverting blood from the tumour.

Examples of bioreductive drugs include tirapazamine (SR-4233) and mitomycin C. The latter is an antitumour antibiotic that is bioreduced to form products that cross-link DNA. It is cell cycle nonspecific, is more toxic to hypoxic than aerated cells, is usually administered i.v. and is rapidly cleared from plasma (half-life, 10–15 minutes). The drug does not cross the blood–brain barrier and the major toxicity is myelosuppression. Indoloquinone EO9 is a synthetic analogue of mitomycin C (MMC), which was expected to have similar properties to MMC, but fundamental differences have emerged; for example, EO9

is a much better substrate for DT-diaphorase (DTD) and it has the ability to redox cycle more readily than MMC after reduction by purified DTD. In addition, EO9 has the ability to increase the cytotoxicity to hypoxic cells 49-fold over MMC. The overall capacity of the tumour to metabolize EO9 has been suggested to be the most important determinant for EO9 activity. This, along with the rapid clearance of EO9 in humans, has been suggested as one of the reasons for the disappointing results obtained from phase II clinical trials.^{9, 10} [****]

Aliphatic amine N-oxides have long been identified as nontoxic metabolites of a large number of tertiary amines drugs. Bioreduction of such N-oxides generate the active parent amine. This principle has been adopted to develop AQ4N, a di-N-oxide anticancer prodrug with little intrinsic cytotoxicity. However, AQ4N is bioreduced in hypoxic regions of solid tumours and micrometastatic deposits to generate a cytotoxic alkylaminoanthraquinone metabolite. The metabolite of AQ4N has high affinity for DNA and is a potent inhibitor of topoisomerase II. Preclinical studies *in vivo* have demonstrated that although AQ4N has little or no intrinsic cytotoxic activity *per se*, it (i) enhances the antitumour effects of radiation and conventional chemotherapeutic agents; (ii) is pharmacokinetically stable; and (iii) is a substrate for cytochrome P450 (CYP). AQ4N is currently in clinical trials.^{11, 12} [***]

In general, as with the hypoxic cell sensitizers mentioned above, there is little clinical evidence from large randomized trials of bioreductive agents showing increased efficacy when combined with conventional radiotherapy.

A number of drugs are currently under preclinical evaluation. Synthetic allosteric modifiers of haemoglobin (e.g. RSR13) are designed to effect a conformational change in the haemoglobin (Hb) tetramer that stabilizes deoxyHb, thereby reducing Hb-O₂ binding affinity. It has been hypothesized that the radioresistant hypoxic regions of tumours might be eliminated if improved O₂ delivery to tumours could be accomplished using its reduced haemoglobin-oxygen (Hb-O₂) binding affinity. In pre-clinical studies, RSR13 has been shown to increase pO₂, decrease intratumoural hypoxia and increase tumour cell killing in animal tumour systems.¹³ [**] The drug is currently under clinical evaluation, primarily for the treatment of brain metastases from breast cancer.¹⁴ OFU is a prodrug of 5-FU, under laboratory investigation, which is activated by capturing hydrated electrons that are produced by hypoxic irradiation. As hydrated electrons are rapidly deactivated by oxygen, the 5-FU release occurs specifically upon hypoxic irradiation.

Certain agents that induce vascular damage (and therefore presumably affect the oxygen status), e.g. hyperthermia or photodynamic therapy, have successfully been combined with radiotherapy to increase tumour cell killing (the reasons for combining these modalities were other than their antivasculature effects). The rationale for

combining therapeutic modalities is based predominately on three concepts: enhanced tumour efficacy, nonoverlapping toxicities, or spatial cooperation. Abnormal tumour microenvironments, tumour progression and metastatic spread of neoplastic cells are all major factors that contribute to radiotherapy failures – all of these may be affected by angiosuppressive or vessel destructive treatments. Antivasculature agents eliminate many of the problems in tumours (e.g. aberrant vascular morphology, spatial heterogeneity metabolic microenvironments, etc.) associated with adverse efficacy of radiotherapy by causing extensive haemorrhagic necrosis in the centre of tumours, i.e. the radiation response is improved by impacting the radiation-resistant hypoxic subpopulation of tumours. Cells surviving treatment using antivasculature agents tend to be located in areas at the tumour periphery near normal tissues; most likely those areas supplied by normal tissue vessels.¹⁵ [****] Such residual tissue is likely to be well oxygenated and therefore sensitive to radiation. A number of preclinical studies have shown that if such combination therapy is used, the tumour's hypoxic cell population can be dramatically reduced or eliminated and a number of investigations have shown that vascular targeting strategies can effectively enhance radiation treatment.¹⁵ [**] Targeting the growth factors that induce new vessel growth may also be effective.^{16, 17} There is also evidence to suggest that certain antiangiogenic agents enhance the effects of radiation by direct effects, i.e. by radiosensitizing endothelial cells.¹⁸ [**] This direct effect, which leads to decreased microvessel density, may have a significant role in enhancing the effect of radiation. The scheduling of such antiangiogenic and antivasculature therapies is an area that is under active investigation as are, since side-effects are minimal in comparison to conventional cytotoxics, clinical biomarkers of efficacy.

ADJUVANT CHEMOTHERAPY

Perhaps a clinically more successful (therapeutic) strategy than trying to overcome hypoxia has been the rather more empirical approach of simply combining 'conventional' chemotherapy with radiotherapy. Squamous head and neck cancers show a clinical response to a number of chemotherapeutic agents, so the strategy of combining such drugs with radiotherapy seems justifiable.

Many randomized trials have been conducted in which a combination of chemotherapy and radiotherapy have been compared with radiotherapy alone. Although the majority of these trials have been relatively small, when combined there are vast numbers of patients, and the technique of 'meta-analysis' has been applied. This has convincingly shown that the addition of chemotherapy does give better results than those achieved with radiotherapy alone.¹⁹ [****] The counterargument has been made that the same could be achieved by simply giving more radiotherapy. However, it is known that beyond a

certain level the incidence of complications rises rapidly if additional radiotherapy is given, which is why the doses used in common practice are as they are. It has proved feasible to give chemotherapy in combination with such doses, and to date, there is no strong suggestion that this does lead to an unacceptable increase in damage to normal tissue. The same cannot be said of the proposed strategy of simply giving higher doses of radiotherapy (other than in the context of fractionation trials, particularly hyperfractionation, as discussed previously).

Combined chemotherapy and radiotherapy schedules have been tested in randomized controlled trials against a policy of primary surgery for moderately advanced laryngeal and hypopharyngeal cancers. In fact, in these trials the drugs have been given before radiotherapy, so are certainly not acting as 'true' radiosensitizers. They have been shown to be no less effective than radical surgery in terms of survival, but confer the advantage of enabling preservation of a functioning larynx in a substantial number of patients. Such 'organ preservation' represents a significant advance in radiotherapy of head and neck cancer, and continue to attract a great deal of attention, with trials of different drug/radiation schedules, and involving other head and neck sites.

There are many chemotherapeutic agents that are effective for head and neck cancer and the possible scheduling combinations of radiotherapy and chemotherapy are numerous. Because of this the meta-analyses have not been able to identify clearly which of the various options is the best, although a strategy of giving cisplatin concurrently or in rapidly alternating sequences, with radiotherapy (perhaps with other drugs as well) is emerging as a front runner. Even so, confirmation that this is the best way of using chemotherapy agents as radiosensitizers is not strong. Drugs other than cisplatin have also been found to add to the effect of radiotherapy in head and neck cancer. The most widely used is fluorouracil, although it is usually used alongside cisplatin. Again, there is debate as to whether it is a 'true radiosensitizer', but combined radiotherapy/cisplatin/fluorouracil schedules are increasingly widely used. Other agents include methotrexate, bleomycin and the taxanes. Of these, there is certainly some evidence that the taxanes are radiosensitizers. The same can be said for the new agent gemcitabine, although clinical experience of the use of this with radiotherapy in head and neck cancer is minimal.

TARGETED THERAPIES

Our understanding of the molecular mechanisms that drive cancer cells has grown at an accelerating pace within recent years. This has led to the emergence of the first wave of drugs that act against cancer cells in a more targeted way than the cytotoxic agents that have been the mainstay of chemotherapy in the past. Because of their

specificity, such agents hold the promise of being much less toxic than conventional chemotherapy.

Among these new classes of agents there are some interesting suggestions of synergy with radiation. In head and neck cancer, one target has so far attracted significant attention, the epidermal growth factor receptor, EGFR (*erbB1*, *HER1*). This is one of a family of transmembrane receptor tyrosine kinases, other members being *HER2/neu* (*erbB2*), *HER3* (*erbB3*) and *HER4* (*erbB4*). Ligand-binding receptor dimerization occurs, which induces a conformational change in the intracellular kinase domain, thereby inducing a cascade of phosphorylation events or activation of signal transduction (e.g. activation of the MAPK or ras signal transduction pathway). As implied by its name and as might be expected in a tumour arising from squamous epithelium, overexpression of this receptor is a very frequent event in head and neck squamous carcinomas. Its overexpression, with or without gene amplification, is often associated with increased production of EGFR ligands, particularly epidermal growth factor (EGF) and transforming growth factor alpha ($TGF\alpha$). Two broad classes of agent have been developed to counteract the way in which the epidermal growth factor receptor signals the cell to proliferate. The first of these, target the extracellular ligand-binding domain using a monoclonal antibody approach. Cetuximab is a chimeric 'humanized' monoclonal antibody that competitively binds to EGFR (it has a 2-log higher affinity for EGFR than $TGF\alpha$ and EGF). Once bound to the receptor, the complex is internalized and the receptor thereby rendered inactive. Cetuximab has undergone clinical trials in head and neck cancer used both as monotherapy and as combined therapy (radiation, chemotherapy). Results from a large randomized phase III trial were very impressive in that improved locoregional control and reduced mortality have been obtained with little increase in toxicity.²⁰ [***] Cetuximab may, in addition to exerting antiproliferative effects by inhibiting the MAPK signal transduction pathway, act as an antiangiogenic agent and therefore exert radiosensitizing effects via mechanisms described above.²¹ [**]

The second approach available to target receptor tyrosine kinases is via the use of small molecules that compete for the ATP binding site of the kinase domain. The low molecular weight of these molecules may allow them to penetrate tumours better and they can be administered orally making them suitable for chronic therapy. Several agents, including gefitinib and erlotinib, have progressed quite far in clinical trials as monotherapy²² [***] and in combination with standard chemotherapy, but little is known regarding their combined use with radiotherapy – it is an area of active investigation. As these agents are very well tolerated, one area that is as yet unresolved is the identification of their optimal dose, i.e. the dose that completely inhibits the receptor rather than the maximally tolerated dose that is conventionally used with standard chemotherapy approaches.

A number of other novel 'radiosensitization' studies are under way (e.g. anti-HER2 antibody-induced radiosensitization, targeting the NF κ B pathway (e.g. by proteasome inhibition using PS-341), *ras* inhibitors, cox-2 inhibitors, etc.), but this area is, as yet, even less developed than the EGFR inhibitors mentioned above and are therefore beyond the scope of this review.^{23, 24, 25, 26, 27} It does appear, however, that 'radiosensitizers' are with us to stay and that their use is set to increase.

KEY POINTS

- Conventional radiotherapy uses photons that both directly and indirectly damage the DNA, through the production of ions and free radicals. The majority of damage induced by photons is via this 'indirect action'.
- Although the DNA is generally considered to be the most important target for radiation-induced damage, this dogma is gradually being amended to include effects on other cellular constituents, particularly cellular membranes.
- Tissues that are dividing rapidly manifest the effects of radiation sooner than those where cell division is slow. In addition to the kinetics (turnover rate) of the population as a whole, the response of tissues and organs is also dependent upon inherent cellular radiosensitivity. The sensitivity of the cell to radiation is determined to some degree by its state of maturity and its functional role; immature rapidly proliferating cells generally being more radiosensitive than slowly proliferating fully differentiated cells.
- The response of a tumour to radiotherapy is dependent upon inherent radiosensitivity, tumour cell repopulation, redistribution through the cell cycle (G2/M is the most sensitive phase of the cell cycle, late-S phase is the most radioresistant), repair of radiation induced damage and reoxygenation of tumour tissues between fractions. These parameters represent the '5 Rs of radiotherapy'.
- A fraction is the individual dose of radiation delivered at a single session of radiotherapy. In the treatment of head and neck cancer, a total course of radiotherapy will take several weeks and comprise numerous fractions. In conventional radiotherapy, fractions are given once a day, five days per week. The fraction size is, almost invariably, constant throughout a course of radiotherapy. Increasing the fraction size tends to have a greater effect (altered severity) on late-reacting as opposed to early-reacting tissues.
- Hypoxic cells (those under low O₂ tension) are relatively resistant to x-rays when compared with fully oxygenated ones. Chronic and acute hypoxia make tumours relatively radioresistant. If such hypoxia is overcome, radiotherapy is more likely to be successful.
- Many approaches to overcome tumour hypoxia are currently under clinical evaluation – these include improving blood flow through the vascularized parts of tumours, tourniquet hypoxia to reduce the radiosensitivity of normal tissues and pharmaceutical approaches to make hypoxic tumour cells more radiosensitive (radiosensitizer drugs).
- The nitroimidazoles have been extensively evaluated as potential radiosensitizers; however, controversy exists of these agents in conventional radiotherapy. So far, only one major randomized trial, of the many that have been performed, has shown a therapeutic benefit (with nimorazole).
- Adjuncts to radiation, which are not true radiosensitizers, include bioreductive drugs. These agents are reduced intracellularly to form cytotoxic agents. A number are under clinical evaluation in head and neck cancers.
- Perhaps a clinically more successful (therapeutic) strategy than trying to overcome hypoxia has been the rather more empirical approach of simply combining 'conventional' chemotherapy with radiotherapy. Combined chemotherapy and radiotherapy schedules have been tested in randomized controlled trials against a policy of primary surgery for moderately advanced laryngeal and hypopharyngeal cancers. Results have been shown to be no less effective than radical surgery in terms of survival, but confer the advantage of enabling preservation of a functioning larynx in a substantial number of patients. Such 'organ preservation' represents a significant advance in radiotherapy of head and neck cancer.
- Meta-analyses have not been able to clearly identify which of the various adjuvant chemotherapy options is the best, although a strategy of giving cisplatin concurrently or in rapidly alternating sequences, with radiotherapy (perhaps with other drugs as well) is emerging as a 'front runner'.
- Novel, molecularly targeted, agents hold the promise of being much less toxic than

conventional chemotherapy. Of the agents under evaluation, Cetuximab, a humanized monoclonal antibody that competitively binds to EGFR, has undergone clinical trials in head and neck cancer used both as monotherapy and as combined therapy (radiation, chemotherapy). Results from a large randomized trial were very impressive in that improved locoregional control and reduced mortality have been obtained with little increase in toxicity.

Methods of detecting and measuring apoptosis	60	References	64

SEARCH STRATEGY AND EVIDENCE-BASE

The data in this chapter are supported by a Medline search using the key words apoptosis, cell cycle, cell signalling, cell cycle. The majority of papers referenced are based on strict histopathological studies and whilst some do not have age- and sex-matched controls, the majority represent level 1 evidence. Some papers referenced are observational and represent level 4 evidence and where these are referenced this will be inserted into the text.

OVERVIEW OF APOPTOSIS

Historical perspective

Apoptosis is a mode of cell death. At the time of Kerr's original description of apoptosis as a distinct phenomenon in 1971,¹ much was already known about cell division, but little attention had been paid to the end of a cell's life.

The word 'apoptosis' is derived from the Greek word for 'falling off', in reference to the falling of leaves from trees in autumn. Much of the early understanding of the molecular biology of apoptosis stemmed from 1980's studies on the nematode *Caenorhabditis elegans*. Ellis and Horvitz² were able to clone the specific genes (*ced* genes) responsible for cell death during the nematode's development. It was already known that exactly 131 cells die during the development of *C. elegans*, however, these normally doomed cells were allowed to survive to maturity by inducing mutations in genes *ced-3* and *ced-4*.³ Close similarities between the nematode *ced* genes and human genes were identified (e.g. *ced-9* and the mammalian oncogene *Bcl-2*⁴) suggesting a function for such mammalian genes in apoptotic pathways.

In the last decade, there has been intense research activity into apoptosis (see **Figure 6.1**). The literature and research can be confusing to the reader because of the pace of change in this field. New genes and gene products are regularly discovered. However, a number of genes, gene products and receptors with separate names may eventually prove to be one and the same but the different names remain in use for some time (e.g. Fas/APO-1/CD95).

Figure 6.1 Apoptosis related scientific publications per annum (Source: Medline).

Apoptosis in cell populations

It is easy to underestimate the relative importance of apoptosis as a physiological, as well as a pathological, event. Daily in the human body millions of marrow cells undergo apoptosis as part of the function of the immune system. Just as a cell population can be varied by cell production, it can also be varied by cell death; **cells can be lost in a number of ways:**

1. **shedding** after terminal differentiation (for example, gut epithelium into the lumen of the bowel);
2. **necrosis**;
3. **apoptosis**.

Whereas **necrosis is always a pathological event as a result of noxious stimuli**, the key importance of apoptosis is that it is the only means of cell loss that can be controlled, both physiologically and genetically. The main differences between apoptosis and necrosis are summarized in **Table 6.1**.

Apoptotic cell loss is now recognized to be fundamental in the regulation of cell populations. This is particularly true in developmental processes and in cell populations with high turnover, such as the intestinal mucosa.

Studies of potential doubling times (T_{pot}) of tumour cell populations would suggest that the growth rate of tumours should be far greater than observed. This necessary cell loss cannot be accounted for by exfoliation or necrosis, and therefore apoptotic cell loss plays an important part in the rate of tumour growth.^{5,6} In fact, tumour growth is a result of the balance between mitosis and apoptosis. The balance between cell division and cell loss is sometimes referred to as tissue homeostasis.

MECHANISMS OF APOPTOSIS

Executors and triggers of apoptosis

A range of stimuli both physiological and pathological can trigger apoptosis (see **Table 6.2**).

The molecular changes during apoptosis are largely governed by a family of at least 14 separate enzymes referred to as caspases (cysteine **aspartate** specific **proteases**). Caspases have a variety of actions (both initiator and effector) including cleavage of DNA and cytoplasmic structure. The two most important pathways of caspase activation (death receptor and intracellular/mitochondrial pathways) share a final common irreversible step in the activation of caspase 3.

Extracellular signalling, death receptors, caspase 8

Cells can be directed to self-destruct by intercellular signals mediated by cell surface receptors that are capable of triggering apoptosis when bound by antibody or ligand molecules. These are known as death receptors (DR). These may allow extracellular signals such as cytokines and hormones to effect apoptosis in target tissue. The death receptors currently recognized include Fas, TNF α receptor 1 and the DR4 and DR5 receptors.

Fas is bound by the extracellular antibody Fas ligand (Fas-L) and this pathway is important in the regulation of the immune system and the deletion of unwanted T-lymphocytes.⁷ Cytotoxic T cells express Fas-L and cause apoptosis by binding Fas receptors on the target cell. Failure of this system (e.g. by Fas mutation) may be implicated in autoimmune disorders.⁸

Table 6.1 Summary of differences between apoptosis and necrosis.

	Apoptosis	Necrosis
Occurrence	Part of physiological or pathological processes	Always pathological
Initiating factors	Range of extracellular and intracellular factors	Direct result of injury and cellular anoxia
Distribution	Isolated apoptotic cells scattered widely throughout tissues	Occurs in groups/whole areas of tissue
Mechanism	Active process – ATP dependent Regulated mechanism	Passive Regulation lost
Cytoplasmic changes	Cytoplasmic shrinkage Blebbing of cell membrane into apoptotic bodies	Swelling of cell membrane Rupture of cell membrane with loss of contents to extracellular space
Nuclear changes	Many organelles preserved and bound into apoptotic bodies Endonuclease activation, cutting of DNA into oligosomal fragments Chromatin condenses into specific 'crescents' visible on light microscopy	Organelles lost Random digestion of DNA Chromatin flocculates
Effect on surrounding tissue	Little or none	Intense inflammation

Table 6.2 Stimuli capable of triggering apoptosis.

	Stimuli
Physical cell damage	Heat
	Free radicals
	UV light
DNA damage	Ionizing radiation
	Alkylating agents
Cell signalling	Steroid hormones
	Interleukins
	Cytokines

Death receptors are trans-membrane proteins with intracellular and extracellular components. Part of the intracellular component is referred to as the death domain (DD). Binding of the extracellular component of the receptor protein leads to binding of the death domain to an adaptor molecule (Fas binds to FADD). This in turn changes the inactive procaspase 8 into the active caspase 8, which itself triggers formation of caspase 3 and ensuing cell death. Although other death receptors bind with different adaptor molecules, the common pathway in death receptor signalling remains activation of initiator caspase 8.

Intracellular signalling, mitochondria and Bcl-2, caspase 9

Although the exact mechanisms are unclear, it is believed that certain stimuli (cell damage, withdrawal of growth factors) effect cell death through a mitochondrial pathway of which the *Bcl-2* family is a key component. Although *Bcl-2* was originally described as a protooncogene in B-cell lymphomas, the family is now known to contain at least 15 proteins that reside on the mitochondrial outer membrane. The family has both pro-apoptotic (e.g. *Bax*, *Bak*) and anti-apoptotic components (e.g. *Bcl-2*, *Bcl-xL*), the balance between the two being crucial in terms of cell survival.

The action of these molecules in triggering apoptosis is to alter the permeability of the mitochondrial membrane, allowing the escape of mitochondrial cytochrome-c. This then binds to the adapter protein Apaf-1 and inactive procaspase 9 to generate active caspase 9, which (like caspase 8) is an initiator of apoptosis.

The cell cycle and apoptosis, p53

Allowing cells with damaged DNA, unreplicated or misaligned chromosomes to replicate by mitosis might lead to daughter cells, which are not only unhealthy or incapable of further division, but potentially neoplastic. To ensure healthy replication of cells there exist cell cycle checkpoints or restriction points, at which

replication can be halted in response to a variety of external signals (stress, growth factors) and internal signals (DNA damage). The first of these occurs between the G1 and S-phase (G1/S checkpoint), the second between G2 and mitosis (G2/M checkpoint).

Progression through the checkpoints is dependent on the expression and function of cyclins (e.g. D1, B1). These can be induced by both extracellular and intracellular stimuli. The upstream pathways leading to cyclin expression are complex and mutations in this system can lead to unregulated passage through the checkpoints.

DNA damage at this point can lead to cell cycle arrest. Two protein kinases, ATM and ATR, are known to be active in the detection of DNA damage. ATM is the protein deficient in the human disease ataxia telangectasia, one of the manifestations of which is increased sensitivity to DNA damage by irradiation.⁹

Expression of ATM and ATR proteins leads to phosphorylation of p53 and hence, through its downstream effector molecules, such as p21, arrest of the cell cycle.

p53 'GUARDIAN OF THE GENOME'

Although a full discussion of the nature and activity of p53 is beyond the scope of this chapter, it occupies a pivotal role in the cell cycle as well as apoptosis induction. Essentially p53 is involved in the detection of abnormal DNA, the decision to cause cell cycle arrest and the decision whether to initiate DNA repair or initiate apoptosis.¹⁰ If DNA damage is irreparable, p53 can, through interactions with the molecules Apaf-1 and Bax , trigger apoptosis by activating caspase 9.

Loss of the ability to express p53 in its native state or the presence of mutated p53 leads to the inability to achieve G1 arrest and the loss of cells' ability to undergo apoptosis in response to DNA damage. The majority of human tumours have inactivation of p53 and *p53* gene mutation is the most common genetic alteration in squamous cell carcinoma of the head and neck (SCCHN).¹¹ Around 65 percent of SCCHN tumours express abnormal amounts of p53 suggesting the presence of mutation.^{12, 13}

Nuclear/biochemical change

As a relatively late event in apoptosis, endonuclease activity cleaves nuclear DNA into fragments of specific length (180 base pairs) known as oligosomal fragments. The specific endonuclease involved in this (caspase-activated DNase or DNA fragmentation factor (CAD/DFF)) is activated by cleavage from its inhibitor, iCAD/DFF45 by caspase 3. The ends of these fragments are specifically 3-OH and 5-P. These oligosomal fragments are an important marker of apoptotic cell death and can be identified by biochemical methods.

Morphological cellular changes

At a nuclear level, widespread DNA fragmentation is associated with the loss of chromatin and its condensation into masses, which form next to the nuclear membrane. This chromatin condensation is regarded as a morphological hallmark of apoptosis and can be seen in light microscopy and electron microscopy as 'crescent' formation within the nucleus. The nuclear membrane itself begins to bleb into nuclear fragments (see Figures 6.2, 6.3, 6.4 and 6.5).

At the same time, there is a reduction in cytoplasmic volume. Organelles are preserved but the endoplasmic reticulum vesiculates can become fused with the cell membrane at various points. In addition, specialized structures on the cell surface become lost and the membrane assumes a smooth and featureless appearance. The cell membrane becomes detached from neighbouring cells as a result of loss of volume and structure. From this point, the cell rapidly fragments into membrane-bound apoptotic bodies, which contain cellular components, such as nuclear fragments. These are short-lived and are

phagocytosed by adjacent cells or macrophages. These changes take place in a matter of hours, although in cell or organ culture it is not clear if the clearance of apoptotic products is as rapid.

METHODS OF DETECTING AND MEASURING APOPTOSIS

Apoptosis may be identified by its morphological or biochemical features (Table 6.3). Some techniques are applicable only to single cell suspensions, others may be used to identify cell death in whole tissues such as sections of pathological specimens.

Morphological identification

Light microscopy using a $\times 100$ oil immersion objective lens is sufficiently sensitive to detect morphological changes, such as cytoplasmic shrinkage, nuclear condensation and apoptotic body formation (Figure 6.6). Haematoxylin and eosin (H&E) is repeatable and uncomplicated and has been used extensively in studies in which identification and quantification of apoptosis is undertaken. Other more specialized tissue stains, such as methyl-green pyronin and Wright staining (Figures 6.2, 6.3, 6.4 and 6.5) may offer some advantages over H&E.

Electron microscopy remains the optimum technique for identification of morphological features of apoptosis. Chromatin condensation (Figure 6.7) and formation of apoptotic bodies are easily seen. However, electron microscopy only allows relatively small amounts of tissue to be examined and its use in quantifying apoptosis in tissue section is limited.

The fluorescent dye acridine orange can identify apoptosis morphologically or part of flow cytometric analysis. However, as the cells examined need to be living, its use is reserved for cell suspensions derived from experiments with cell culture.

Biochemical identification

Flow cytometry allows a variety of measurements to be made concerning a cell population, including changes in

Table 6.3 Identifying features of apoptosis.

Morphological	Biochemical
Cytoplasmic shrinkage from surrounding cells	Externalization of phosphatidyl serine
Nuclear condensation and pyknosis	180 base pair oligosomal DNA fragments
Chromatin condensation and crescent formation	3-OH ends of oligosomal fragments
Formation of apoptotic bodies

Figure 6.7 Electron micrograph of nasal polyp stroma cells after incubation with dexamethasone, demonstrating margination of chromatin and 'crescent' formation.

cell size, DNA and chromatin structure. A variety of methods of identifying apoptotic cells using flow cytometry have been described, one of the most common techniques is to attempt to identify a pre-G1 peak when the number of cells in each phase of the cell cycle is counted using propidium iodide as a nuclear stain.

Endonuclease-mediated division of DNA into oligosomal fragments is easily identified by the appearance of a ladder of bands in multiples of 180 bp on agarose gel electrophoresis.

Apoptosis can be identified in tissue sections by labelling the characteristic free 3-OH termini of DNA fragments with a modified nucleotide, mediated by the terminal deoxynucleotidyl transferase (TdT) enzyme or DNA polymerase. This is referred to as *in situ* end labelling (ISEL) or TdT-mediated nick end labelling (TUNEL). The technique is available in commercially produced reagent sets. However, although end labelling may be used in archived tissue sections, 'staining' problems can arise with varying ages and fixation times of samples.

Annexin-V is a phospholipid which binds to phosphatidylserine residues. Early in the apoptotic process these are flipped from the inner to the outer cell membrane. Annexin-V can be identified by immunoassay and detects an earlier stage of apoptosis than end labelling for DNA fragments.

APOPTOSIS IN DISEASE

Much research in the last decade has aimed at identifying apoptosis (or failure of apoptosis) as a part of the pathogenesis of specific diseases. In fact, as apoptosis is such a fundamental part of normal tissue function, it should not be surprising to discover that apoptosis

can be identified at some stage in most disease processes. In some diseases, failure of apoptosis regulation (see Table 6.4) is more fundamental than others in which apoptosis is merely one step in a larger pathological process.

Apoptosis in non-neoplastic disease

CONGENITAL DEFECTS

Certain cells are destined to die by apoptosis before birth as a part of normal development and maturation, a classical example being the cells in the tail of a tadpole. Failure of apoptotic mechanisms or abnormal apoptotic activity is implicated in a variety of congenital abnormalities, including cardiac defects and cleft palate.

VIRAL INFECTION

A cell's normal response to infection would be to die. However, viral genes may encode proteins, which mimic the host cell's own antiapoptotic proteins to artificially prolong the life of an infected host cell.¹⁵ This allows the virus more time in which to replicate. In other situations, viruses act by inducing apoptosis in host cells, the human immunodeficiency virus (HIV) virus causes apoptosis in infected CD4⁺ lymphocytes in the acquired immunodeficiency syndrome (AIDS).¹⁶

SENSORINEURAL DEAFNESS

It seems likely that most sensorineural hearing loss is likely to be mediated by apoptotic loss of hair cells and

inner ear structures. The cochleas of gerbils treated with the ototoxic doses of cisplatin demonstrate apoptosis in the organ of Corti, the spiral ganglion, and the stria vascularis.¹⁷ In the inner ear of the senescence-accelerated mouse, apoptosis has been identified in inner and outer hair cells as well as in the saccules, suggesting that this is the way in which these cells are lost in presbycusis.¹⁸ Apoptosis is also implicated in the differentiation of cells in the developing inner ear.¹⁹

EOSINOPHIL APOPTOSIS AND NASAL POLYPS

Apoptosis is thought to be an important process in the reduction of inflammatory cell numbers and resolution of inflammatory processes and eosinophil apoptosis is delayed in allergic inflammation. Resolution of asthma attacks after treatment with corticosteroids is accompanied by apoptotic cell death in eosinophils and their subsequent engulfment by macrophages.²⁰ Although corticosteroid-induced eosinophil apoptosis can be seen *in vitro* in explants of nasal polyp tissue, this effect has not yet been demonstrated in clinical trials.²¹

The potential action of steroids on inflammatory cells in nasal polyps may be indirect, reducing the production of cytokines, such as interleukin (IL)-5. Cytokines IL-3, IL-5 and granulocyte-macrophage colony-stimulating factor (GM-CSF) have an antiapoptotic effect on eosinophils (possibly mediated through Bcl-x) and this effect is inhibited by glucocorticoids. Notably, relative to other cytokines IL-5 is significantly upregulated in nasal polyps.²²

Fas/FasL mediates a separate pathway for eosinophil apoptosis; stimulation by an anti-Fas monoclonal antibody leads to eosinophil apoptosis and resolution of airway inflammation.²³ Fas expression is greater in nasal polyp tissue and this may have implications in the pathogenesis of the condition.²⁴

THYROID DISEASE

The Fas/Fas-L mechanism of apoptosis induction is important in the pathogenesis of autoimmune disease. Immunoprivileged cells, such as thyrocytes, express Fas-L and are able to cause apoptosis by binding to Fas receptors on selfreactive lymphocytes and preventing themselves being killed. Failure of this mechanism can lead to autoimmune disorders. Alternatively, IL-1 β (a cytokine produced by infiltrating macrophages) can induce Fas expression in thyrocytes themselves which then causes thyrocytes to kill each other.^{25, 26} In this way, an autoimmune process might be triggered by infection. Conversely, the antibody responsible for Grave's disease and the hormone TSH downregulate Fas expression,²⁷ leading to an increase in thyrocyte numbers and thyroxine production.

APOPTOSIS AND CANCER

Apoptosis and carcinogenesis

As apoptosis is the way in which the body deletes cells with abnormal DNA, then **neoplastic change may accompany failure of apoptotic mechanisms.**²⁸ As well as the mutations in p53 already discussed, mutations affecting the genes coding for other components may also be associated with cancer. Many of these components (e.g. Bcl-2, Bax, Apaf-1, p21) can be identified in tissue sections by immunoassay. However, interpretation of the significance of their expression in head and neck cancer is more difficult.

Apoptotic indices in cancer

In studies of head and neck cancers, in the progression from dysplasia through carcinoma *in situ* to invasive carcinoma, there is an increase in mitosis but no change in the apoptotic index.²⁹ Effectively, the apoptosis/mitosis ratio falls with progression towards increasing malignancy. The relative position of apoptotic and mitotic events in the epithelium also differs in that with increasing malignancy, mitoses tend to shift towards the basal layer, whereas apoptotic events, normally located in the basal or stem cell layer, become more superficial.³⁰

Numerous studies investigated the fraction of cells undergoing apoptosis (apoptotic index, AI) in tumours. The relationship between AI and outcome measures, such as recurrence after radiotherapy and survival, varies with different tumours and in different series. Such studies in head and neck cancer are summarized in **Table 6.5**.

The exact mechanism by which the apoptotic index is related to outcome remains unclear. There are a number of potential explanations and these are outlined below.

APOPTOTIC INDEX AS A MEASURE OF CELLULAR TURNOVER IN TUMOURS

Rates of apoptosis and mitosis are generally highly correlated and as such, AI may be regarded as an index of cell turnover in a tumour population. In this case, AI would correlate negatively with survival, as tumours with high proliferative indices generally have a poorer prognosis. Indeed, the frequency of mitotic figures helps to determine the degree of differentiation of a tumour. Poor differentiation is known to be associated with high apoptotic index in head and neck cancer.³⁶

LOSS OF APOPTOTIC MECHANISMS WITH INCREASING MALIGNANCY

If one accepts that a cell population's ability to undergo apoptosis is important in the removal of abnormal cells, then a higher frequency of apoptotic bodies might suggest

Table 6.5 Studies of apoptosis and outcome in laryngeal carcinoma.

Study	Site of cancer studied	Treatment modality	Number of patients	Method of identification of apoptosis	Relationship of increasing AI to prognosis
Hotz <i>et al.</i> ³¹	All head and neck	Radiotherapy, surgery, chemotherapy	26	TUNEL	Negative

^aInvestigated induction of apoptosis by radiotherapy.

that the population of tumour cells still has the ability to police itself and highly abnormal cells could be removed. As tumour cell lines become more poorly differentiated and lose normal apoptotic mechanisms, such as normal p53 function, they will become more aggressive and survival will be poorer.

APOPTOSIS IS INCIDENTALLY RELATED TO OUTCOME

Poorly differentiated and aggressive tumours have large areas of poor blood supply and necrosis. Apoptosis is noted to be more common in areas adjacent to necrotic foci³⁷ and areas of hypoxia are more common in larger tumours, suggesting that any relationship between apoptosis and outcome is an epiphenomenon. Hypoxic and poorly perfused tumours are radioresistant³⁸ and apoptosis can itself be a reaction to hypoxia rather than a function of malignant change.

Radiotherapy and apoptosis

If apoptosis is induced by nuclear damage, then it might be assumed that the devastating nuclear effects of ionizing radiation at radiotherapy treatment doses would lead to widespread apoptosis. However, the main mode of cell death in irradiated tissues is reproductive or mitotic cell death, in which the cell is unable to complete replication and dies in mid-division.³⁹ Apoptotic cell death after radiation appears to have greater significance in haemopoietic cells than in epithelial tissue. *In vitro* studies with cell lines suggest the dose of radiation required to induce apoptosis varies considerably (2.5–25 Gy). It is of interest that the apoptotic response is related to the rate of regression with treatment⁴⁰ and the preirradiation or natural apoptotic index for a tumour is related to the apoptotic response to radiotherapy.⁴¹ The maximum fraction of cells that may be induced into apoptosis is only around 40 percent,⁴² suggesting that not only are the

remainder radioresistant, but confirming that there are other modes of cell death involved in the radiotherapy response. Kraxner reported that the greater induction of tumour cell apoptosis after the first 2 Gy of radiotherapy in head and neck cancer patients was associated with increased survival.³⁵ The fraction of cell death induced by radiotherapy may be of relatively greater importance in 'fractionated' radiotherapy.⁴³

Apoptosis is also responsible for some of the side effects of radiotherapy, such as the loss of cells in irradiated lacrimal and salivary glands.⁴⁴

Chemotherapy and apoptosis

It is likely that all chemical agents currently used to kill cancer cells in clinical practice do so by in some way triggering the apoptotic pathway.⁴⁵ After a cell recognizes drug-induced damage as irreparable (for example, the detection of DNA damage by p53), apoptotic pathways are activated. In addition, some agents directly activate components of the apoptosis pathway; bleomycin and doxorubicin upregulate expression of Fas and Fas ligand.⁴⁶

To a greater or lesser extent, these mechanisms rely on the presence of normal apoptotic pathways for their execution. It is known that some cells are more resistant to chemotherapy apoptosis than others because of their relatively slow turnover.⁴⁷ However, abnormalities in the apoptotic mechanisms in tumour cells may underlie the majority of chemotherapeutic drug resistance. Tumours with p53 mutations are known to be less chemosensitive. Overexpression of the antiapoptotic BCL-2 in chronic lymphocytic leukaemia leads to relative resistance to fludarabine and mitoxantrone.⁴⁸ Breast and prostate cancer cell lines can have their chemosensitivity enhanced by gene transfer of wild type p53.⁴⁹ Restoration of normal p53 function to cancer cells is one form of gene therapy, which is discussed in Chapter 3, Gene therapy.

SEARCH STRATEGY AND EVIDENCE-BASE

The data in this chapter are supported by a Medline search using the key words stem cells, pluripotent stem cells, regeneration, multipotent cells and differentiation. The majority of papers referenced are based on strict histopathological or immunocytochemical studies that represent level 1 evidence. Some papers referenced are statements that are based on expert opinion and are level 4 evidence and where this occurs this will be inserted into the text.

STEM CELLS

Disease or therapy in otorhinolaryngology-head and neck surgery may both result in the destruction or malformation of tissues and organs such as nasal cartilages, pinna and trachea. Reconstructing an injured face is a prime example of when such damage may occur. The ability to regenerate adult teeth, or cochlear hair cells to restore hearing would offer massive benefits. There is a growing hope that stem cells, derived from either adult and embryonic sources, may have therapeutic potential, but much research is required before their use is commonplace.

Human embryonic stem cells can be maintained in tissue culture as immortal cell lines with the potential to differentiate into any cell in the body, or by incorporation

into a blastocyst to give rise to a new individual.^{1,2} They offer great potential as therapeutic agents to repair traumatized tissues, regenerate whole organs or to treat diseases such as diabetes, Alzheimer's or Parkinson's disease and congenital disorders such as immune deficiencies. Problems and concerns about their use include the question of immune compatibility, worries about their origins from aborted human foetuses and the question of how to regulate their differentiation accurately.

Adult stem cells are present in every tissue and may be manipulated to differentiate into a range of cell types. These cells may be isolated, multiplied in culture and then used as homografts to treat problems in their donor without risk of immune rejection or ethical concerns.

PROPERTIES OF STEM CELLS

Every human tissue includes a population of cells capable of entering the mitotic cycle to produce daughter cells which can differentiate and carry out tissue replacement or growth. These are stem cells, and their essential characteristic is asymmetric division; one of the daughter cells remains undifferentiated and potentially immortal. Stem cells may also undergo proliferative divisions to expand the stem cell population. Recent technical developments permit the isolation of stem cells from any tissue and it has been a surprise to find that even in the central nervous system where neurons are not normally replaced, stem cell lines can be isolated that generate neurons as well as glial cells.

STEM CELL NICHES

Stem cell function depends on maintaining a stable population of stem cells which may be activated when required and whose daughter cells can gain access to appropriate regions of the tissue. This requires a tissue niche where stem cells are grouped for control of their self-renewal and differentiation.³

Specificity of the niche environment depends upon paracrine signalling from supporting cells, formation of gap junctions with supporting cells, and on localized extracellular matrix molecules, such as heparin sulphate proteoglycan (HSPG)⁴ which bind cytokines, fibroblast growth factors (FGF) and other signalling molecules. In general, experimental activation of stem cells to engineer their multiplication involves removing them from the stabilizing influence of the niche environment, as well as exposing them to stimulating growth factors.

In bone marrow, transplanted labelled haemopoietic stem cells form uniformly sized clusters on the stroma⁵ in association with a class of stromal cell which supports human stem cells but does not allow their expansion.⁶ In mouse hair follicles, the melanocyte niche has been identified in the lower part of the follicle, occupied by a group of stable, immature, differentiation-competent stem cells.⁷ If hepatocyte proliferation is blocked in the liver, regeneration may still occur by multiplication and differentiation of oval cells released from a niche on the biliary ducts.⁸ A niche for adult neurogenic stem cells has been identified in the adult subventricular zone (SVZ).⁹ Cells of the SVZ express bone morphogenetic protein (BMP) which suppresses neurogenesis and so maintains the undifferentiated stem cells. Nearby ependymal cells, however, express Noggin which antagonizes BMP and so stimulates neurogenesis. Cells from this niche migrate to form interneurons in the olfactory bulb.¹⁰

ACTIVATION OF STEM CELLS IN ADULT TISSUES

Maintenance of an adult tissue requires a perfect balance between cell death and the production of new replacement cells. The slightest inequality between cell loss and stem cell activation would quickly lead to tissue hypertrophy or atrophy. A further demonstration of the environmental control of stem cell activation is that stem cells transferred to new environments demonstrate a competence to differentiate into other tissue types.

Stem cells are activated under different circumstances for tissue maintenance or for tissue repair. Tissue maintenance in the simplest case employs local feedback systems where differentiated cells signal stem cells to inhibit their proliferation. Activation for tissue repair may reflect the exposure of heparin-binding growth factors such as FGF-2, signals from macrophages as part of the inflammatory reaction and paracrine signals from the damaged cells. In a recent analysis of this question Frye *et al.*¹¹ used gene array technology to follow epidermal stem cell activation triggered by c-myc expression. Classes of genes whose expression was upregulated included genes involved in cell proliferation and differentiation, and in RNA and protein synthesis and processing. A large proportion of downregulated genes coded for cell adhesion molecules and cytoskeletal proteins. These findings signify that stem cell quiescence requires stable interactions between stem cells and their supporting cells in the niche, and activation involves release from this stabilization.

An interesting question in stem cell biology is why adult tissues may contain stem cells capable of generating cells which are never seen to be replaced *in vivo*. For example, stem cells isolated from rat spinal cord can differentiate into motoneurons,¹² but regeneration of mammalian motoneurons has never been described in humans nor in animal models of human regeneration. Similarly, stem cells have been isolated from mouse vestibular organs which differentiate into hair cells when implanted into chick otic vesicles,¹³ although hair cells are not known to regenerate naturally in mammals.

Growth factors signals for proliferation

ASYMMETRIC DIVISION

Tissues that undergo continuous cell replacement throughout life retain stable numbers of stem cells. Stem cells divide asymmetrically to produce two daughters, one which will undergo many symmetrical divisions to produce a large population of differentiated offspring, and the other another stem cell. It is possible, however, for a stem cell to undergo proliferative division to produce more stem cells, or for surplus stem cells to undergo apoptosis, in order to retain appropriate numbers of

stem cells. This can be illustrated by reconstitution of haemopoietic stem cells in bone marrow following x-irradiation to treat lymphoma. The number of stem cells in the regenerated bone marrow is independent of the number injected into the blood stream.

Understanding the genetic mechanisms for this regulation is founded on experiments with *Drosophila*, followed by recognition of homologous genes in mammalian tissues. These experiments demonstrate two principle mechanisms: segregation of proteins into the prospective stem cell during asymmetric cell division; and a system of interactive signalling between prospective stem cells and prospective differentiation-competent daughter cells.

Drosophila neural stem cells divide asymmetrically into another neuroblast, and a ganglion mother cell (GMC) which is cleaved once into two neurons. The neural fate determination proteins *Numb* (which suppresses *Notch* signalling) and *Prospero* (a transcription factor) are localized to the basal surface of the stem cell. To coordinate mitotic spindle orientation with the polarized localization of the neural fate determinants, the apical surface is defined by localization of *Inscutable* and *Bazooka*, and the basal surface by *Lethal giant larvae* and *Lethal discs large*¹⁴ so that when the cell divides, proteins in the basal compartment segregate to the GMC.

Interactive signalling between daughter stem cells and GMC is mediated by the *Notch-Delta* system. Lateral inhibition of stem cells by their surrounding daughter cells maintains them in a nonproliferative state.^{15, 16}

SPECIFICITY OF STEM CELL DIFFERENTIATION

Stem cell differentiation within healthy adult tissues is tissue-specific, and new cells are appropriate in type, location and number. This does not, however, mean that adult stem cells are necessarily restricted to a single fate, because under experimental circumstances many examples are known where differentiation into cell types not present in the tissue of origin is determined by a community effect. Isolated stem cells, exposed to a sufficient number of differentiated cells from another tissue, differentiate into cells of the new tissue. Human neural stem cells allowed to aggregate with human myoblasts, differentiated into myoblasts.¹⁷ It was essential to disaggregate the neural cells; as long as they remained in contact with one another, their neural competence was conserved. Similarly, embryonic human endothelial cells cocultured with cardiomyoblasts can differentiate into cardiac myocytes.¹⁸ Rat spinal cord stem cells, which in tissue culture differentiate only into glial cells, when implanted into rat hippocampus formed granule cells.¹⁹ The concept of community effect was first formulated in relation to embryonic myogenesis.²⁰ It appears to involve tissue-specific paracrine signalling and in the case of muscle several candidate signalling molecules have been proposed.^{21, 22}

A single stem cell population may generate several cell types, as seen in haemopoiesis in bone marrow or in the basal layer of the epidermis. In the epidermis, stem cells may differentiate into sebaceous gland cells, hair follicle cells or keratinocytes. Within a developing hair follicle, cells must migrate to be exposed to determination factors which initiate differentiation into a hair.¹¹

Although human embryonic stem (ES) cells are pluripotent, within a developing embryo they differentiate into cell types appropriate for different embryonic tissues in an orderly way. Differentiation specificity is determined by environmental signals. For example, if human ES cells are cocultured with stromal cells from bone marrow, they differentiate into haemopoietic stem cells.²³ If they are treated with FGF-2, a growth factor important in regulation of brain development (reviewed in Haik *et al.*²⁴), a substantial proportion aggregate and differentiate into neural tube-like structures. If these aggregates are later dispersed into single cells and cultured without FGF-2, they differentiate into neurons and glia. Similarly, if they are transplanted into the brain of a newborn mouse they differentiate into neurons and astrocytes within apparently normal brain structures.²⁵

STEM CELLS AND EXPRESSION OF CONNEXINS

Connexins are a family of proteins which form gap junctions, permitting the movement of ions and small molecules between the cytoplasm of adjacent cells. The expression of connexins is often used as a marker to define the transition between a stem cell and its differentiated progeny. Lack of expression of connexins is also considered to be evidence of malignancy in neoplastic cells.

The connexin family consists of at least 14 different proteins, making it technically difficult to categorically define their absence. Also, they are expressed by supporting cells within a stem cell niche,²⁶ leading to the hypothesis that they may be necessary for stem cell activation. Stem cell proliferation was normal in tissue from connexin-43 null-mutant mice, casting doubt on this proposal,²⁷ although other connexin isoforms are also expressed by these cells.²⁸

STEM CELL HIERARCHIES

Stem cells have traditionally been classified in a hierarchy. The fertilized egg and its progeny from the first three cell divisions are totipotent. One of these cells placed in a woman's uterus has the potential to develop into a foetus.

As embryonic development proceeds, the totipotent cells multiply to form the spherical blastocyst, with an outer layer of cells committed to form the placenta and other extra-embryonic tissues and an inner cell mass which forms the embryo. Cells of the inner cell mass are pluripotent embryonic stem cells. They can give rise to

any body tissue, but if implanted into a uterus do not form a new individual as they have lost the capacity to form extra-embryonic tissues. Maintenance of pluripotency is associated with expression of the homeobox protein *Nanog*, a transcription factor which drives the expression of other proteins required to maintain the pluripotent state.^{29, 30}

Human pluripotent embryonic stem cell lines isolated either from blastocyst inner cell masses² or from foetal testes or ovaries¹ appear to have similar properties, including the potential to give rise to a new human being, although for ethical reasons none has yet been permitted to express this potential. One reason for their isolation is their potential for supporting tissue regeneration in adults. This potential is now overtaken by the finding that pluripotent cells may be isolated from adult tissues, a possibility that escapes the ethical problems associated with the embryonic tissues, as well as the problem of immune rejection. Immortal tissue culture cell lines of pluripotent mouse embryonic stem cells have created the thriving industrial production of transgenic mice: a blastocyst is isolated from a normal mouse, genetically modified cultured embryonic stem cells are injected into the inner cell mass, and the blastocyst reimplanted into a surrogate mother. If descendants of one of the modified cells enter the germline to become oocytes or sperm it is then possible to isolate a new strain of mice in which every individual has the genome of the tissue culture cell.

As an embryo develops through the stages of gastrulation and neurulation, pluripotent cells are segregated into ectoderm, mesoderm and endoderm, and then into particular tissues such as brain, muscle, bone or gut. Stem cells in these tissues are multipotent, being committed to generate cells to form each particular tissue in an orderly manner. Finally, multipotent stem cells may give rise to tissue-specific committed stem cells, which generate only one cell type.

This orderly hierarchical classification: totipotent, pluripotent, multipotent and committed, validly describes normal tissue growth and maintenance, but is not absolute. It has become commonplace to discover that stem cells which *in vivo* are multipotent or committed, when isolated from their host tissue and transferred to a different environment express pluripotent characteristics. For example, skeletal muscle has a resident stem cell population known as satellite cells. When these are activated to enter the cell cycle they support muscle growth or regeneration by differentiating into myoblasts which fuse with multinucleated muscle fibres. If a biopsy sample of human muscle is minced and placed in normal tissue culture medium, satellite cells multiply and form multinucleated striated muscle fibres in the tissue culture dish. If, however, an appropriate growth factor is added to the culture, the muscle stem cells differentiate into bone or adipose tissue. Adult muscle tissue also includes a separate population of stem cells which can reconstitute haemopoietic tissue in an x-irradiated host.³¹

Stem cells within different levels of their hierarchy have different levels of competence to respond to growth signals. The currently best understood system is that of haemopoietic stem cells, capable of generating progeny which may differentiate into any of the cells of the blood, osteoclasts or dendritic cells. These occupy a complex niche environment in bone marrow where they interact with a three-dimensional network of stromal supporting cells and extracellular matrix, bone spicules and blood vessels. Haemopoietic stem cells can be classified as true progenitor cells, intermediate progenitors and mature progenitors, which are acted upon by three corresponding classes of growth factors, classes I, II and III, respectively. In tissue culture assays, class I factors which include stem cell factor (SCF) and interleukin-1 (IL-1) do not support colony formation on their own, but in the presence of class II and III factors support the formation of very large clones which may contain all the classes of haemopoietic cell formed by bone marrow. Class III factors (granulocyte-colony stimulating factor (G-CSF), macrophage-colony stimulating factor (M-CSF), erythropoietin) stimulate mature stem cells to form small colonies, and act on the differentiated cells to enhance their functions; for example increasing the adhesiveness of neutrophils. Class II factors (interleukin-3 (IL-3), granulocyte-macrophage-colony stimulating factor (GM-CSF)) can induce colony formation with fewer mature stem cells, but the addition of class III factors is necessary for stem cells to become fully functional.

CARCINOGENETIC POTENTIAL OF STEM CELLS

Stem cells have the capacity to generate large numbers of progeny cells and share with malignant carcinoma cells properties such as expression of telomerase and lack of expression of connexins. It is important to consider whether their use as therapeutic tools is associated with a concurrent risk of cancer.

The stem cell theory of cancer suggests that many or most cancers arise from defects in stem cell growth control,³² although this theory does not imply that normal stem cells are malignant. Normal cells respond to growth controls and apoptotic signals, are competent to differentiate and to respond adaptively to environmental conditions and eventually become senescent. Stem cells and their derivatives, after disaggregation and grafting into a new environment, appear generally to behave as normal cells in these regards, but if they are implanted as a cell mass they may be less able to respond to local growth control signals. A commercial cell line of mouse embryonic stem cells transplanted into an embryo as a cell mass may form a mass of undifferentiated cells or even a teratoma.³³ One or a few of the same cells injected into the inner cell mass of a blastocyst can participate in generating a normal mouse, indicating their competence to respond to signals regulating growth. Similarly, the fate

of stem cells isolated from adult tissues including human breast, kidney, brain or pancreas can be either neoplastic or committed to normal differentiation, according to how they are manipulated.³⁴

There is little evidence for stem cells exhibiting cancer-like properties, and more evidence for the contrary view.³⁵ Stem cells are exquisitely sensitive to growth regulation from their environment and have several mechanisms to retain the integrity of their genome. Mechanisms to maintain the integrity of a stem cell genome include segregation of template and daughter DNA,³⁶ incompetence for DNA repair and apoptosis of cells with errors in template strands. Selective retention of template DNA strands following mitosis so that the copied strands are passed to the daughter cell whose progeny will eventually differentiate, greatly reduces the possibility of copying errors entering the stem cell population. A further mechanism to conserve the integrity of the genome is lack of competence to repair random DNA damage, so that the stem cell undergoes apoptosis rather than risking a DNA repair error.³⁵

PLURIPOTENT STEM CELLS MAY BE ISOLATED FROM ADULT TISSUES

A small population of bone marrow cells which home to bone marrow in irradiated hosts³⁷ are not only capable of repopulating the bone marrow stem cell niche, but can also differentiate into cells of the liver, gastrointestinal tract, lungs and skin. A subpopulation of blood monocytes have similar properties.³⁸ Stem cells isolated from aspirates of human adipose tissue can be induced to form bone by exposure to BMP³⁹ or myocytes by exposure to 5-azocytidine.⁴⁰ The human olfactory bulb contains undifferentiated stem cells and their homologues from rats or mice can be induced to differentiate into many neural and glial cell types, and when mixed with myoblasts may differentiate into muscle.⁴⁰ Haemopoietic or neural stem cells, implanted into mouse blastocysts, become incorporated into multiple tissues but with some preference for blood or brain, respectively.⁴¹ Hair follicle cells have the competence to form haemopoietic tissue.⁴²

Much remains to be learned of the hierarchy of control mechanisms regulating stem cell competence, but the examples given above typify evidence that apparently committed cells can be induced to become multipotent or even totipotent, offering avenues for therapy with autologous tissues.

NERVES AND STEM CELL ACTIVATION

Many instances are known where denervation results in tissue atrophy or failure to regenerate. A classic example is an amputated urodele amphibian limb which will regenerate only if the nerve is intact.⁴³ The long-sought

neurotrophic factor may be a member of the neuregulin family.⁴⁴ Human taste buds are continually shed from the tongue and replaced by proliferation and differentiation of basal cells. This process depends on the integrity of the sensory innervation of the tongue. Following partial hepatectomy, proliferation of hepatocytes is impaired if the vagus nerve is sectioned,⁴⁵ an observation which may explain the lower rates of hepatocyte proliferation seen in transplanted livers. If skin is denervated, the epidermis is thinned and keratinocyte proliferation is reduced.^{46, 47, 48} Healing of experimental bone fractures in rat hindlimbs is significantly impeded by section of the sciatic nerve.⁴⁹ Denervated skeletal muscles suffer profound atrophy and numbers of foetal myoblasts or early postnatal satellite cells are severely reduced following denervation.^{50, 51}

The idea that nerves influence regeneration and healing is deeply embedded in medical tradition and was responsible for early theories of neurotrophism. Its true importance and its mechanisms are still obscure. The slowing of wound healing in denervated skin may be the consequence of reduced infiltration by macrophages in the absence of nociceptor-induced tissue inflammation, with a consequent reduction in macrophage-released tissue growth factors.⁵² Muscle nerves have a clear neurotrophic influence on post-synaptic receptors,^{53, 54} but many other influences of nerve on muscle may simply be activity-dependent. Gustatory nerve terminals signal basal cells in taste buds via a paracrine pathway to upregulate basal cell expression of the mammalian analogue of *Drosophila* achaete-scute proneural gene complex, *Mash 1*, and induce the differentiation of taste receptor cells in the tongue.⁵⁵

Despite its prominence in stem cell activity, the neural dependence of bone marrow function has received little attention. Bone marrow receives both autonomic and sensory innervation. Blood flow to bone marrow is strongly influenced by haemopoietic activity, apparently regulated by cytokines released from bone marrow cells, rather than by autonomic neural control.⁵⁶ A recent study⁵⁷ showing depression of immune function and of haemopoiesis in patients with complete spinal cord transections supports the idea that bone marrow function is neurally regulated, but details of mechanism are yet to be discovered.

TELOMERASE ACTIVITY IN STEM CELLS

A feature of the mechanics of DNA replication is that DNA sequence at the ends of a chromosome is not fully replicated, so that unless there is some form of repair, chromosomes progressively shorten by 70–90 bp with each mitotic cycle. Chromosome ends are capped with telomeres, specialized structures made up of characteristic DNA repeat sequences and a complex of associated proteins. In most somatic cells, each cell division cycle results in telomere shortening, whereas in germ cells and stem cells, telomere lengths are conserved. The primary

mechanism for preventing telomere attrition and hence protecting cells from senescence is activation of telomerase. This is a ribonucleoprotein complex with two major components, human telomerase reverse transcriptase (hTERT) and human telomerase RNA (hTR). The RNA provides a template for telomeric repeat synthesis, allowing telomerase to catalyze the addition of TTAGGG repeats to the chromosome end.

During embryogenesis, telomerase levels typically fall and activity is absent in most adult human somatic cells. Telomerase can be used as a marker to help identify stem cells in adult tissues, but cells with functional competence to act as stem cells do not necessarily express high levels of telomerase.⁵⁸ A considerable number of experiments have used viral constructs to express telomerase and hence rescue stem cell function, with varied results. Tissue transplants from aged donors may consist of cells with relatively short telomere lengths and little competence to regenerate in their new host. In some cases, transfection with an expression vector for hTERT resulted in immortalized tissue culture lines with the potential to act as effective tissue transplants. For example, cells in human adrenal cortex proliferate throughout life and adrenals do not have a stem cell or basal cell compartment. Telomere lengths progressively shorten, and cell proliferative capacity is lost. Adrenal cortical cells can be immortalized by transfection with hTERT making them possible effective candidates for transplantation,⁵⁹ although the possibility that they might be malignant would need to be checked.

Cells in some tumours have telomeres of normal or greater than normal length, but no telomerase activity. Here, telomere lengths are retained by a separate mechanism (alternative lengthening of telomeres (ALT)) employing homologous recombination.⁶⁰ Utilization of ALT is associated with the presence of ALT-associated promyelocytic leukaemia bodies (APB) which contain human telomere repeat sequences and DNA recombination enzymes⁶¹ giving a histological marker for ALT-positive cells. These have not been observed in normal stem cells.

EMBRYONIC ORIGINS OF STEM CELLS

Whether or not stem cells in adult tissues are leftovers from embryonic development or whether they should be considered as having a distinct adult phenotype, is a question which probably does not have a general answer. Muscle satellite cells amplified in tissue culture and reimplanted in place of embryonic myogenic cells cannot recapitulate the process of embryonic development of muscle.⁶² Conversely, satellite cells do not form in Pax-7 null-mutant mice, but embryonic and foetal development of muscle appears to be normal.⁶³ Thus in this case, satellite cells are specialized adult muscle stem cells, not leftover embryonic stem cells. Muscle does, however, include another stem cell population with a larger range of competence and these are possibly endothelial stem

cells which migrated into muscles during the formation of muscle vasculature.⁶⁴

This example from skeletal muscle appears part of a general case. Tissues may have tissue-specific stem cells, often part of a highly organized tissue structure, and may also include stem cells of endothelial or haemopoietic origin which have arrived in the blood circulation. The roles of tissue-specific cells in tissue maintenance are most easily recognized. Activation of blood-borne stem cells may only be evident in the case of severe tissue damage. They have generated great interest with their obvious potential for clinical manipulation to promote healing of tissues which do not normally regenerate.

The developmental origins of primate neural stem cells were investigated by injecting human neural stem cells into the brain ventricles of foetal monkeys.⁶⁵ Some of the injected cells were integrated into brain structures, while others populated the subventricular zone, a source of stem cells in the adult brain. The authors suggest that adult stem cells are the end result of a developmental program rather than representing prolonged embryogenesis.

STEM CELL MIGRATION

Many, perhaps most, embryonic precursor cells migrate from their site of origin to their ultimate tissue residence where they will multiply and differentiate. Thus, when considering transplantation into an adult or activation of stem cells resident in adult tissues, it is not surprising to find that these too may migrate and integrate into adult tissues in an orderly and constructive manner. Neural stem cells provide some robust examples. Human neural stem cells injected into the cerebral ventricles of a monkey foetus integrated into the ventricular germinal zone from where they either migrated along radial glia to their appropriate cortical target zone, or remained as an undifferentiated population in the subventricular zone with a potential for later activation.⁶⁵ If implanted into adult tissue, neural stem cells were attracted to migrate towards degenerating neural tissue.⁶⁶ The attractant molecule was identified as stromal cell-derived factor 1 α , an inflammatory chemoattractant molecule common to many pathologies. Imitola *et al.*⁶⁶ propose a general model where tissue injury evokes chemoattractants which activate and attract resident stem cells and direct their migration to the site of injury. These cells would inhabit injury-induced stem cell niches where potentially reparative signals were transiently expressed. Once entered into the injury site, the stem cells express antiinflammatory molecules,^{67, 68} leading to stabilization of the injury response.

STEM CELL-RELEASED GROWTH FACTORS

Stem cells not only have the potential to multiply and differentiate to generate new tissue, they also release

growth factors which may support healing and regeneration. As an example, dopaminergic neurons were lesioned with a selective neurotoxin (a mouse model for Parkinson's disease) and then mouse neural stem cells were implanted into one side of the midbrain.⁶⁹ Dopaminergic neural function was partially restored and most dopaminergic neurons were identified as rescued host neurons, rather than differentiated grafted neurons. Evidently this was due to secretion of a neuroprotective factor or factors by the grafted stem cells. An assay of growth factors and cytokines secreted by bone marrow-derived mesenchymal stem cells⁷⁰ revealed a multiplicity of factors including interleukins, leukaemia-inhibitory factor and stem cell factor. If the cells were induced to differentiate into different cell types, such as osteoblasts, adipocytes or endothelial cells, many of these growth factors continued to be expressed. In addition, tissue-specific growth factor secretion was upregulated, for example osteopontin in osteoblasts and vascular epithelial growth factor in endothelial cells.

REGENERATION OF HUMAN TISSUES

The capacity to regenerate organs or appendages is scattered throughout phylogeny and even where regeneration occurs, closely related species may lack this ability.⁷¹ Some coelenterates can regenerate a new organism from a body fragment or even a single cell. Many, but not all urodele amphibia, such as the axolotl, can regenerate a limb; an adult newt can regenerate limbs, tail, upper or lower jaws, neural retina or lens, and even portions of the heart; and humans may regenerate a severed finger-tip.⁷²

Mechanisms of tissue or organ regeneration comprise two principle classes. First, differentiated cells may dedifferentiate, multiply and then redifferentiate. Second, the tissue may include a reserve of stem cells which may be activated and produce a population of differentiation-competent daughter cells, as well as retaining a constant reserve population of stem cells.

The spectacular examples of organ regeneration in urodele amphibia depend on the first of these mechanisms. Dedifferentiated cells multiply to form a blastema, an aggregate of undifferentiated cells with the capacity to differentiate into any of the cell types necessary to regenerate the organ. These cells re-express embryonic patterning genes, for example *Pax-6* during eye regeneration,⁷³ and region-specific Hox genes,^{74,75} growth factors important in regulating embryonic tissue development, such as members of the FGF family,^{76,77} and dorsal-ventral patterning genes⁷⁸ during limb regeneration.

Mammalian cells are capable of similar dedifferentiation, even if in many tissues this does not normally occur. Identification of mammalian homologues of genes expressed in newt blastemas⁷⁹ may help identify targets for therapeutic interventions in people. Transgenic expression

of the homeobox gene *msx-1* in tissue-cultured mouse muscle cells triggers them to dedifferentiate and fragment into mononucleated cells with the capacity to proliferate and differentiate into bone, adipose tissue, muscle or cartilage.⁸⁰ In humans, liver hepatocytes and vascular smooth muscle cells are examples where dedifferentiation—redifferentiation are part of everyday tissue maintenance and growth. In the liver, every hepatocyte is able to divide and to regenerate liver tissue following hepatectomy.⁸¹

CELLS FOR TISSUE MAINTENANCE HAVE TWO POSSIBLE ORIGINS

It now appears that every tissue in the body includes a population of stem cells, but the degree to which these are employed in everyday tissue maintenance varies considerably.

Dedifferentiation, cell multiplication and redifferentiation are characteristic of several tissues, notably liver, smooth muscle and peripheral nerve Schwann cells. In a healthy liver, hepatocytes are constantly replaced and at any one moment around 8 percent are in a proliferative state,⁸² indicating a half-life of about ten days. Tissues with stem cell niches employed in tissue maintenance include blood, skin and mucosa, olfactory epithelium and bone. The principle function of satellite cells in skeletal muscle is to support post-natal muscle growth,⁶³ but they can be activated to support adult muscle regeneration.

BONE MARROW HAS TWO POPULATIONS OF MULTIPOTENT CELLS

Bone marrow contains two different types of multipotent cells. Mesenchymal stem cells populate the bone marrow stroma and have the potential to give rise to mesodermal tissues, such as bone, cartilage, adipose tissue and skeletal muscle cells. Haemopoietic stem cells generate cells of the blood and immune system.

Circulating bone marrow cells have been shown to contribute to regeneration in many tissues including heart,⁸³ skeletal muscle,^{84,85} endothelium,^{86,87} liver^{88,89} and skin.⁹⁰ The ease with which they can be isolated and their capacity to home to damaged tissues to promote regeneration make them attractive candidates for therapeutic tools.⁸⁵

POSSIBLE THERAPEUTIC USES FOR STEM CELLS

Stem cell therapy is still largely confined to laboratory models but is rapidly approaching clinical utility. How may these therapies be applied?

First, and perhaps most obvious, endogenous stem cells may be activated to promote tissue regeneration to

compensate for trauma, disease or ageing. Some tissues contain stem cells with little potential for natural activation *in vivo*, but which can be activated experimentally; these include articular cartilage, neurons and adult teeth. Activation might involve their removal and isolation, multiplication and replacement *in vivo*, or alternatively may be achieved by local application of specific growth factors. Examples at the research level are isolation and multiplication of neural stem cells,⁹¹ of chondrogenic cells to repair articular cartilage,^{92, 93} and of vestibular hair cells to restore balance or hearing.^{13, 94}

Second, endogenous stem cells may be removed and cultured on a substrate to generate an organ rudiment, which may then be grafted back into the patient. An example of current application is for skin grafts to treat burns patients, and at the research level, attempts to engineer tooth buds to replace adult teeth.⁹⁵ An extension of this approach is to genetically engineer the isolated cells before amplification and replacement, for example with a construct which might express a necessary growth factor. An example is to express BMP in osteogenic stem cells to induce cartilage repair.⁹⁶

A third application is to use stem cell therapy to compensate for genetic disorders. Much effort has been applied to Duchenne muscular dystrophy (DMD) with the hope that skeletal muscle stem cells expressing a normal dystrophin protein might be targeted to degenerating muscles in DMD patients, but technical hurdles have not yet been overcome.

Potential stem cell therapies are being considered for a wide range of pathological conditions and diseases, including neural stem cells to replace neurons lost in ageing or dementia; pancreatic islet cells in diabetics; specialized glial cells to promote regeneration of peripheral nerves or long fibre tracts in the central nervous system (CNS); chondrogenic stem cells to repair cartilage, bones and joints; stem cells to replace cochlear hair cells; tooth germs to regenerate teeth and many others.

THERAPEUTIC USE OF EMBRYONIC STEM CELLS

Embryonic stem cells are isolated from the inner cell mass of the preimplantation blastocyst^{2, 97} and have been derived from mice, nonhuman primates and humans. They are pluripotent cells, retaining the capacity to generate any and all foetal and adult cell types *in vivo* and *in vitro*.⁹⁸ These cells can be maintained and expanded *in vitro* in an undifferentiated, pluripotent state almost indefinitely in the presence of leukaemia-inhibitory factor (LIF) or embryonic fibroblasts. This provides a potentially unlimited source of stem cells. If LIF is withdrawn, ES cells spontaneously differentiate to form cellular aggregates or embryoid bodies, which contain differentiating cells of ectodermal, endodermal and mesodermal lineage. ES cell differentiation pathways can be controlled and

restricted by manipulation of culture conditions to generate cultures enriched for lineage-specific precursors. The generation of a range of distinct phenotypes from mouse ES cells, including haematopoietic precursors,⁹⁹ neural cells,¹⁰⁰ adipocytes,¹⁰¹ muscle cells,¹⁰² myocytes,¹⁰³ chondrocytes¹⁰⁴ and osteoblasts¹⁰⁵ has been achieved using this approach.

Other sources of pluripotent stem cells are embryonic germ (EG) cells derived from the gonadal ridge of the early foetus,¹⁰⁶ embryonic carcinoma (EC) cells derived from teratocarcinomas,¹⁰⁷ and mesenchymal stem cells from placental cord blood.¹⁰⁸

Isolation of human ES cells^{1, 2} now makes it possible that human ES cells can be developed for tissue repair and regeneration. Differentiation protocols developed for mouse ES cells are likely to be relevant to human ES cells¹⁰⁹ as even though there are differences in their morphology, propagation and culture requirements, they are broadly similar in their potential to differentiate into specific cell types.

There are a number of ways to control ES cell differentiation and preferentially select a particular phenotype. A relatively simple approach is to culture in media supplemented with cytokines, hormones or other factors that stimulate the cell type of interest. This requires detailed knowledge of the biology of the cell type of interest, but this biochemical selection approach is relatively effective. Osteoblasts can be generated from mouse ES cells and derivation of osteoblasts was demonstrated by simply maintaining dispersed embryoid bodies in a culture medium routinely used to culture explanted mouse osteoblasts. On refining the culture conditions, it was found that whilst the biochemical composition of the medium in which the differentiating ES cells are maintained was an import stimulus for selecting the osteoblast phenotype, the timing of stimulation was also crucial. Thus, by delaying the addition of one particular factor, in this example dexamethasone, for up to 14 days after dispersal and culture of the embryoid bodies, a seven-fold enrichment of cells capable of expressing the osteoblast phenotype was attained.¹⁰⁵ Coculture with mouse osteoblasts is an effective inducer of osteogenic differentiation in ES cells. There are unpublished reports from other workers to show that implantation of human ES cells into mouse organs and tissues, including brain and liver, is an effective method to induce neural or hepatic phenotypes. Such observations are consistent with those on adult stem cells and further emphasize the influence of environment on stem cells and the acquisition of a particular phenotype.

Biochemical selection, although useful for generating cultures enriched with a particular phenotype, does not effectively exclude other phenotypes. Approximately 60–70 percent enrichment of cells with osteoblast lineage was found in experiments at the Tissue Engineering and Regenerative Medicine Centre (TEC), with the remaining cells comprising a mixed population of other phenotypes, such as neural cells. Methods to further purify or select

cells of the desired lineage/phenotype need to be developed if ES cells are to be considered for use for transplantation therapy. Methods such as fluorescence-activated cell sorter (FACS) or magnetic-activated cell sorter (MACS) are useful to sort and purify a particular cell type or population. A cell surface marker expressed by the cell type of interest that can be recognized by a fluorescence or magnetic microbead tagged antibody is used to preferentially select that cell. To be effective, the cell surface marker should be restricted to the desired cell lineage and ideally should not be sensitive to activation upon binding of the tagged antibody. FACS and MACS have been used to purify osteoprogenitors from marrow stromal stem cells.

As an alternative, stem cells (both ES cells and adult stem cells) can be transduced with a lineage-specific gene. In this knock-in approach, the gene insert can also carry one of several resistance genes which allow for preferential selection of cell subpopulations that should be restricted to the lineage of interest. This method has been used to select neural¹¹⁰ and cardiomyocyte phenotypes.¹⁰³ In the latter example, the selected cardiomyocytes were subsequently implanted into the damaged hearts of mice and shown to form stable grafts.¹¹¹ The potential to use ES cells for tissue repair and regeneration could be enhanced by using nuclear transfer to make the cells autologous and so remove risks of tissue rejection, or by using human ES cell lines with modifications to the major histocompatibility complex.

Human ES cells are derived by growing cleavage-stage embryos into blastocysts and then removing the inner cell mass. The embryos from which the initial human ES cell lines were derived were produced by *in vitro* fertilization and donated with the informed consent of the parents. The use of such 'spare' embryos was widely held to be acceptable. As they were created for reproductive purposes for which they were no longer required, it was considered ethically superior to use them for medical research rather than destroying them or storing them. Another way to derive human embryonic stem cells is by somatic nuclear transfer or cloning. In nuclear cloning an enucleated oocyte is fused with the nucleus of a somatic cell which can go on to generate an intact embryo and produce a viable organism that is genetically identical to the donor of the somatic nucleus.¹¹² The factors and mechanisms that induce this remarkable transformation are not known, but it seems likely that a component of the enucleated oocyte can initiate rewinding of the genetic programme of the somatic nucleus to generate a 'totipotent cell'.

Human ES cells show several morphological and behavioural differences from murine ES cells. They grow more slowly and tend to form flat rather than spherical colonies. Differentiating human ES cell cultures include cells with several distinct morphologies including neurons, epithelium and cardiomyocytes. As with murine ES cells, manipulating the culture conditions under which the cells are kept can encourage the differentiation of

different cell lineages. Specific local influences, through coculture with mature cells can also encourage the formation of a particular lineage.

The potential use of human ES cells to create cell populations, tissues or organs for implantation through the use of therapeutic nuclear transfer or other methods, could revolutionize medicine by providing unlimited material compatible with the patient's own tissues. The cells might also be used as *in vitro* systems for studying the differentiation of specific cell types and for evaluating new drugs and identifying new genes as potential therapeutic targets.

POTENTIAL THERAPEUTIC USE OF CELLS ENGINEERED TO SUPPORT REGENERATION

Olfactory ensheathing cells are a class of glial cells which support regeneration of olfactory receptor neurons in the olfactory epithelium. When transplanted to other regions of the brain they may support regeneration of other classes of neurons.¹¹³ They also support axon regeneration and have been successfully employed in rat models of spinal cord regeneration.^{114, 115}

Periosteal stem cells and muscle stem cells have been engineered to express BMP, Sonic hedgehog (Shh) or vascular endothelial growth factor (VEGF) and then used in animal models of bone repair.^{96, 116} Expression of the growth factors improved the quality of repair.

Examples of stem cell use to promote tissue regeneration

OLFACTORY SYSTEM

The mammalian olfactory system has the distinction of being the only part of the CNS undergoing continuous renewal. Olfactory receptor neurons have half-lives of a few weeks and are renewed by division of stem cells in the olfactory epithelium which give rise both to neurons and to supporting cells.^{117, 118} Their number is selfregulated by secretion of inhibitory factors, including GDF-11¹¹⁹ and FGF and BMP¹²⁰ from the olfactory neurons. Newly generated receptor neurons extend axons through the cribriform plate to accurately reinnervate particular olfactory glomeruli specific for each odour receptor type (ca. 400 in humans, ca. 900 in rodents). Their regeneration is promoted by growth factors secreted by olfactory ensheathing cells (OEC) located beneath the olfactory epithelium.¹¹³ OEC are a form of glia and there is much interest in their possible therapeutic use to stimulate axon regeneration in other regions of the brain.^{113, 114, 115, 121}

Not only are olfactory receptor neurons continuously renewed, but also their target neurons in the olfactory bulb. These form from neural stem cells in the subventricular zones of the lateral ventricles,¹²² and then

migrate as a chain of neural precursor cells^{10, 123} to form neurons in the olfactory bulb.

USE OF CHONDROCYTES FOR TISSUE REPAIR

Although articular cartilage has a low capacity for repair, mesenchymal stem cells with the capacity to form cartilage, bone or adipose tissue can be extracted from it.⁹² Autologous transplantation of amplified stem cells to repair damaged cartilage is reported to have good outcomes,^{124, 125} which may in future be enhanced by engineering them to express growth factors⁹⁶ and by transplanting them embedded in a matrix rather than in suspension.^{126, 127}

Human nasal septum is a good source of chondrogenic cells with the potential to be used to engineer transplants for restorative surgery in otolaryngology.¹²⁸

REGENERATION OF ADULT TEETH

The casting of 'baby' teeth and their replacement with adult teeth is part of normal human development and it is reasonable to speculate that it will be possible to induce a second round of tooth development. Development of teeth depends on an epithelial-mesenchymal interaction which employs highly conserved genetic signalling mechanisms, common to the formation of many other tissues (see <http://bite-it.helsinki.fi> for an up-to-date summary).

Embryonic tooth morphogenesis critically depends on the migration of cranial neural crest cells into the first branchial arch.¹²⁹ Their odontogenic potential is realized in response to signalling molecules from the oral epithelium including Shh, BMP and FGF.

Adult human odontogenic stem cells have been isolated from dental pulp tissue.¹³⁰ Tooth morphogenesis can occur in a number of experimental systems *in vitro* giving potential to generate tissue for experimental therapeutic use.^{131, 132}

REGENERATION OF SKIN

Autografts of cultured epidermal cells are commonly used to treat burns patients, although several limitations remain to be overcome. In particular, several weeks are required to amplify cells taken from the patient and the grafted skin does not include hair follicles. To create a skin-equivalent tissue suitable for grafting, organotypic coculture of keratinocytes together with skin fibroblasts offers promise.¹³³ In a model system, rat hair follicle dermal cells acted as stem cells that could reconstitute both dermis and hair follicles, offering promise for clinical use.¹³⁴

COCHLEAR HAIR CELLS

Normal hearing depends on the integrity of around 3500 inner hair cells in each cochlea. These cells are generated

early in the embryo, during the first trimester. After that time they are not normally capable of renewal or regeneration, and must survive for an individual's entire life. Hair cell loss is the most common cause of deafness and is currently irreversible. In birds, by contrast, new inner hair cells are generated following loss or injury,¹³⁵ giving hope for therapeutic intervention in humans.¹³⁶

In both birds and mammals, the auditory epithelium includes differentiated hair cells with an orderly spacing among supporting cells, similar in many respects to other sensory organs in which receptor cells are regenerated from the supporting cells. This is what occurs in birds, but following loss of a hair cell in mammals the supporting cells form a scar. If, however, the sensory epithelium is disaggregated, stem cells with competence to differentiate into hair cells (and other cell types) can be isolated.¹³ Further definition of the signalling systems responsible for their quiescence and activation may allow development of therapies for deafness and loss of balance.

NEURAL STEM CELLS

There have been many efforts to use tissue grafts of dopaminergic cells to treat Parkinson's disease, but these have not yet proved to be clinically useful,¹³⁷ although intraventricular injection of neural stem cells in a mouse model offers promise.⁶⁹ Many other proposals exist to use neural stem cells to treat degenerative diseases and stroke or to ameliorate the effects of ageing and are currently being trialled in animal models.

Use of stem cells for organ replacement

Examples from urodele amphibia, where multipotent blastemal cells can regenerate limbs, heart or retina, inspire hope that stem cell therapies may be developed to regenerate entire human organs. This goal currently is achieved only with blood, for example reconstituting haemopoietic tissue following whole body irradiation to treat leukaemia.

One approach is to immunoisolate the grafted tissue by confinement in a diffusion chamber, for example in experimental treatment of diabetes.¹³⁸ This technique imposes severe restrictions on tissue size as tissues are not directly perfused with blood.

Use of stem cells to treat genetic disorders

Treatment of congenital disorders requires either replacement of an affected cell type or supplementation of the functions of a defective tissue. Replacement of haemopoietic tissue, for example, to treat congenital immune system disorders or anaemias is effective in animal

models¹³⁹ and is being applied clinically.¹⁴⁰ Stem cell therapies to treat disorders of other tissues have yet to be developed. Considerable effort has been applied to find strategies to treat Duchenne muscular dystrophy, but these are limited by the global distribution of skeletal muscle in the body and the necessity to destroy existing muscle before any successful multiplication of grafted muscle stem cells will occur.

KEY POINTS

- Human embryonic stem cells have the potential to differentiate into any cell in the body.
- Embryonic stem cells have therapeutic potential.
- Difficulties in applying embryonic stem cells therapeutically include tissue rejection, controlling their differentiation and ethical concerns.
- Stem cells are present in every tissue.
- Adult stem cells may be multipotent and offer better therapeutic potential than embryonic stem cells.
- Properties of stem cells:
 - potentially immortal due to asymmetric division;
 - stem cells are found in all tissues;
 - occupy a 'niche' where their numbers are regulated to remain relatively constant throughout life;
 - surplus stem cells may undergo apoptosis so as to retain their appropriate number;
 - may be activated to undergo mitosis to support tissue growth, repair or maintenance;
 - asymmetric division: one daughter cell remains undifferentiated and potentially immortal;
 - differentiated phenotype is strongly influenced by environmental signals;
 - stem cells do not express connexins or form gap junctions.
- Traditional definition of a hierarchy of stem cell potency:
 - totipotent (has the potential to develop into a whole organism);
 - pluripotent (can give rise to any cell in the body);
 - multipotent (committed to generate the cells of a particular tissue);
 - committed (can generate only one cell type).
- Stem cell carcinomas are not a likely outcome of stem cell therapy:
 - stem cell proliferation responds to signals that regulate growth;
 - embryonal carcinomas typically are benign: metastases occur only after secondary transformation to malignancy.
- Stem cells possess several mechanisms to preserve the integrity of their genomes:
 - segregation of template and daughter DNA to selectively retain template DNA in the stem cell lineage;
 - inactivation of DNA repair mechanisms;
 - apoptosis of cells with errors in template strands.
- Recently, pluripotent stem cells have been isolated from adult tissues:
 - multipotent or committed stem cells in an appropriate environment or treated with appropriate growth factors behave as pluripotent stem cells.
- Two principle mechanisms underly the regulation of stem cell number:
 - segregation of some classes of protein into the prospective stem cell during asymmetric cell division;
 - interactive signalling between prospective stem cells and prospective differentiation-competent daughter cells.
- Stem cells occupy a tissue niche:
 - stem cells are grouped for control of their self-renewal and differentiation;
 - specificity of the niche environment depends both on paracrine signalling from supporting cells and on local extracellular matrix molecules, such as heparin sulphate proteoglycan, which bind cytokines, FGF and other signalling molecules.
- Stem cell activation may require innervation:
 - denervation may result in tissue atrophy and failure to regenerate;
 - the idea of a neural influence on regeneration and healing is deeply embedded in medical tradition, but its true importance and mechanisms are still obscure.
- Differentiation of intrinsic stem cells is tissue-specific:
 - stem cell fate can be experimentally modulated by disaggregating stem cells (so they no longer contact one another) and exposing them to a different environment.
- Many, but not all, stem cells express telomerase:
 - telomere lengths are conserved during stem cell division;
 - telomerase is a ribonucleoprotein complex with two major components: human telomerase reverse transcriptase and human telomerase RNA;

- telomerase RNA provides a template for telomerase repeat synthesis, catalyzing the addition of TTAGGG repeats to the chromosome end to restore telomere lengths after each cell division.
- Tissues may have stem cell populations with multiple embryonic origins:
 - tissue-specific adult stem cells distinct from embryonic stem cells;
 - endothelial stem cells which have migrated into the tissue during the formation of the vasculature;
 - stem cells from bone marrow which have arrived via circulation of blood.
- Stem cells are capable of migration:
 - most embryonic precursor cells migrate from their site of origin to their ultimate tissue residence;
 - adult stem cells retain the capacity for orderly migration and integration into tissues.
- Stem cells release growth factors:
 - their release from grafted stem cells may support healing and regeneration in host tissues.
- The capacity to regenerate organs or appendages is scattered throughout phylogeny:
 - some urodele amphibia can regenerate whole limbs, jaws, neural retina or portions of the heart;
 - closely related species may greatly differ in their competence to regenerate;
 - regeneration often depends upon the formation of a blastema which may be derived from a reserve of stem cells, or by dedifferentiation of tissue-specific cells;
 - blastemal cells re-express embryonic patterning genes.
- Cells for tissue maintenance have two possible origins, dedifferentiation, multiplication and redifferentiation; or activation of tissue-specific stem cells:
 - liver hepatocytes, vascular smooth muscle cells and peripheral nerve Schwann cells are examples of tissues which regenerate via dedifferentiation;
 - blood, skeletal muscle and skin are examples of tissues regenerating from tissue-specific stem cells.
- Bone marrow has two populations of multipotent cells:
 - mesenchymal stem cells occupy the bone marrow stroma and give rise to mesodermal tissues including bone, cartilage, adipose tissue and skeletal muscle cells;
 - haemopoietic stem cells generate cells of the blood and immune systems;
 - circulating bone marrow cells have been shown to contribute to regeneration in many tissues including heart, skeletal muscle, endothelium, liver and skin.
- Possible therapeutic uses for stem cells include:
 - regeneration within damaged tissues;
 - organ replacement;
 - compensation for genetic disorders;
 - cells engineered to express growth factors or hormones.
- Two major approaches to therapy are: (1) activation of stem cells *in situ* and (2) isolation, multiplication *in vitro* and grafting of amplified stem cells back into the donor or into a new host:
 - some tissues contain stem cells with little potential for natural activation *in vivo* but which can be activated experimentally; these include articular cartilage, neurons, vestibular hair cells and adult teeth;
 - multiplication *in vitro* is routine in production of skin for grafting and is in experimental development for other tissues.
- Therapeutic use of embryonic stem cells isolated from human embryos poses immunological and ethical concerns:
 - as with any organ transplant, there is a risk of tissue rejection;
 - there is public resistance to using cells or tissues from aborted foetuses, or to collecting fertilized ova specifically to generate cells for transplants;
 - isolation of embryonic stem cells from placental cord blood or the use of 'universal' human embryonic stem cell lines may alleviate ethical concerns.
- Examples of potential therapeutic use of cells engineered to support regeneration:
 - olfactory ensheathing cells to promote axonal regeneration across spinal cord lesions;
 - engineered expression of bone morphogenetic protein or Sonic hedgehog by periosteal stem cells to promote cartilage regeneration;
 - use of muscle-derived stem cells engineered to express bone morphogenetic protein or vascular endothelial growth factor to promote bone healing.
- Examples of stem cell use to promote tissue regeneration:
 - reconstitution of olfactory epithelium;
 - use of chondrocytes for cartilage repair;

- use of odontogenic adult stem cells to regenerate adult teeth;
- regeneration of dermis using epidermal stem cells expanded in culture;
- restoration of hearing by regeneration of hair cells in the organ of Corti;
- neural stem cells.
- Examples of stem cell use to promote organ replacement:
 - reconstitution of haemopoietic tissue;
 - endocrine cells in diffusion chambers to treat diabetes and other endocrine dysfunctions.
- Using stem cells to treat genetic disorders:
 - dystrophin and Duchenne muscular dystrophy;
 - haemopoietic disorders: restoration of immune competence.

Deficiencies in current knowledge and areas for future research

Potentially immortal stem cells can be isolated from every human tissue. Stem cell tissue culture lines can also be created from inner cell masses of human blastocysts or from human foetal gonads. These cells have the competence to differentiate into multiple cell types and the potential to support regeneration of any adult human tissue.

In tissues where stem cells are active in tissue maintenance or can support tissue regeneration following damage, stem cells occupy niche environments where their numbers can be maintained and their activities regulated. Stem cells possess special mechanisms to preserve them from genetic damage and to selectively eliminate cells with mutated DNA. In contrast with malignant cells, stem cells are exquisitely sensitive to multiple growth control mechanisms and preserve the integrity of their genomes. Adult resident stem cell populations derive from developmental programs and are not simply left over from embryonic development of each tissue. Adult tissues may also include stem cells which have arrived in the blood circulation, derived from both embryonic and adult endothelial or bone marrow cells.

Stem cell biology is an extremely active and expanding field of research with annual publications in the thousands. The popular press is replete with articles promising new technology to regenerate tissues, reverse neurodegeneration or produce designer children. These possibilities are not yet applicable to human subjects, although housing designer mice has become a problem for most laboratory animal facilities.

Deeper understanding of the mechanisms of stem cell activation may generate technologies for controlled

regeneration of particular tissues, using their intrinsic stem cell populations. The demonstration that bone marrow-derived cells can be activated to differentiate into specific cell types and to home to particular tissues offers the possibility of stimulating tissue regeneration by intravenous infusion of appropriate cell populations. Cultured stem cells may be surgically grafted into sites where regeneration is required. One can only speculate on the speed with which these speculations can become clinical reality.

Possible future directions include:

- tissues of special interest to otolaryngology include bone, cartilage, mucosal epithelia, epidermis, vestibular and cochlear hair cells, nerve and brain, skeletal muscle, teeth and vascular tissues;
- enhanced activation of intrinsic adult stem cells: teeth, articular cartilage, brain, blood vessels, wound healing;
- homografted and heterografted stem cells: skin, hair, blood;
- use of embryonic stem cells to regenerate limbs or other body parts.

SEARCH STRATEGY AND EVIDENCE-BASE

The data in this chapter are supported by a Medline search using the key words wound healing, tissue repair, wound assessment, chronic wounds and wound dressings. The data are based on levels of evidence 1 and 2 and clinical recommendations are grades B and C.

INTRODUCTION

The term 'wound' can be defined as a bodily injury, in which there is disruption of the normal continuity of structures resulting from physical, chemical or thermal damage, or developing as a result of the presence of an underlying physiological disorder. It is an event associated with a loss of substance, and a corresponding impairment of function.¹ Wound healing is the restoration of tissue continuity after injury² and it involves wound closure and restoration of function to the damaged tissue.

Injured tissue heals by either partial or complete regeneration, or by repair. Regeneration implies a complete re-establishment of the original tissue structure. In humans, tissues which have the power to regenerate, include epithelium (including the epidermis, alimentary tract epithelium and tracheobronchial epithelium), liver parenchyma, bone, smooth muscle and some skeletal muscle. Tissues and organs, such as the dermis, which are incapable of responding to injury by regeneration, undergo a process of repair in which the original tissue is replaced with nonspecific connective tissue, which forms a functionally inferior scar. The scar tissue

performs few of the specialized functions of the original tissue, but serves to hold together the remaining tissue. However, even in this capacity, scar tissue is less effective than the tissue it replaces, having a reduced tensile strength and energy absorbing capacity, which may be associated with the arrangement of its collagen fibres.³

An injury to the skin results in the epidermis being regenerated and the dermis being repaired by replacement with scar tissue. Skin is therefore an interesting structure in which to observe wound healing, because both these processes of regeneration and repair occur upon injury, it is a frequent site of injury, and access to the skin for experimental purposes is relatively easy.

It was a Greek physician, Galen (129–199BC), who identified two forms of wound healing – primary and secondary intention – depending on the physician's aim in treating the wound. The primary intention of the physician was seen as approximating the wound edges so that minimal scar formation would result. With gaping wound edges, loss of tissue had to be compensated by the formation of new connective tissue and wound contraction, often resulting in cosmetically and functionally inferior scar formation.

© Hodder Arnold / Scott-Brown 7E

Galen's notions are still valid in modern medicine and healing is still divided into two types – healing by first and second intention.

HEALING BY FIRST INTENTION

Healing by first intention is seen in clean, well-perfused, incised surgical wounds (**Figure 8.1**) and casual wounds inflicted by sharp-edged objects, where there is minimum destruction of tissue, the edges being closely apposed shortly after injury, where healing occurs without complication.

Epithelial proliferation occurs rapidly (within 24 hours) sealing the wound at the level of the basal cells of the epidermis. Apposition of the wound edges decreases the distance that the cells need to migrate. There is also minimal granulation tissue formation, so that the end result is an intact epithelium (regeneration), and a small fibrous scar (repair) – the most satisfactory result following injury.^{2,4}

HEALING BY SECOND INTENTION

Healing by second intention is seen when the wound is large (**Figure 8.2**), where there has been significant loss or destruction of tissue such that the edges cannot be apposed, or when complications such as infection occur.

Thus, secondary healing is indicated in the case of gaping wounds with lacerated edges, large defects that cannot be covered by grafting, extensive trophic disturbances such as leg ulcers, highly suppurative wounds, wounds interspersed with foreign bodies, infected wounds that have undergone primary closure and wounds that heal better cosmetically and functionally as a result of contraction rather than sutures, e.g. fingertip injuries.

In these situations, sealing of the epithelium across the wound does not occur rapidly, since the cells have to grow down and spread progressively across the wound at the junction of viable and nonviable tissue. There is also more granulation tissue formation growing from the base of the wound to fill the defect, accompanied by wound contraction, so that the end result is an intact epithelium

Figure 8.2 A typical venous leg ulcer. Image provided by TVU.

(regeneration), but more tissue distortion and an extensive, cosmetically unsatisfactory scar, which often causes an impairment of function (repair).^{2,4}

In mammalian skin, this type of tissue injury initiates a complex, but orderly, series of biochemical and cellular events which, influenced by a large number of chemical mediators, leads to haemostasis, wound healing and the eventual generation of the scar tissue. The repair process can be arbitrarily divided into three main overlapping and inter-relating phases,⁵ namely:

1. inflammation;
2. new tissue formation (proliferation);
3. matrix formation and remodelling.

It should be emphasized that there is no clear demarcation between the phases of wound healing; the process of tissue repair being a continuous phenomenon.

Inflammation

Inflammation can be defined as a localized protective tissue response elicited by injury or destruction of tissues, which serves to destroy, dilute or wall off both the injurious agent and the injured tissues. The acute inflammatory response, which usually extends from the onset of injury to approximately the fourth day of healing, generates an environment conducive to the generation of granulation tissue, and is similar whether the causative agent is a microbial infection (e.g. pyogenic bacteria, viruses), hypersensitivity reaction (e.g. due to parasites, tubercle bacilli), physical agent (e.g. trauma, ionizing irradiation, heat, cold), chemical (e.g. corrosives, acids, alkalis, reducing agents, bacterial toxins) or tissue necrosis (e.g. ischaemic infarction).² It must be remembered that some of the above may be iatrogenic in origin.

Tissue injury causes both cell death and vessel disruption. The most obvious results of the inflammatory

phase are ridding the injured area of debris and necrotic tissue, and the local reduction of infection. This process of inflammation is an essential part of the reparative process and can be temporally divided into early and late phases.⁵

EARLY INFLAMMATION

This is characterized by clot formation, both within damaged vessels resulting in cessation of haemorrhage and within the wound void, providing a provisional matrix of fibrin, fibronectin, von Willebrand factor (vWF) and thrombospondin,^{6, 7, 8} which facilitates the early migration of cells into the wound environment,⁹ stimulates fibroblast proliferation (via thrombin), and shields mitogenic and chemotactic factors from inhibitors.¹⁰

During this process of clotting, haemostasis is enhanced by a five to ten-minute period of vasoconstriction, thought to be initiated by platelet-induced mediators which modulate vascular tone and permeability.¹¹ Additional activities of platelets are mediated by the release of an array of biologically active substances that stimulate the synthesis of extracellular matrix components (ECM) and consequently initiate the subsequent phases of repair, and also promote cell migration and ingrowth to the site of injury.¹² These substances include platelet-derived growth factor (PDGF),^{13, 14} platelet factor 4 (PF4),¹⁵ transforming growth factor alpha (TGF α)¹⁶ and transforming growth factor beta (TGF β).¹⁷

In addition to its role in haemostasis, blood clotting is a crucial part of inflammation, because activation of Hageman factor leads to the generation of bradykinin,¹⁸ and to the initiation of the classical and alternative complement cascades,¹⁹ generating the complement-derived anaphylatoxins C3a and C5a.²⁰ Bradykinin and the anaphylatoxins increase the permeability of the uninjured local blood vessels,²¹ resulting in the release of plasma proteins and the generation of an extravascular clot. The mechanism by which bradykinin increases vessel permeability is thought to involve an induction of prostaglandin production.²²

The anaphylatoxins also stimulate the release of the vasoactive mediators histamine and leukotrienes (LT) C4 and D4 from mast cells,²³ the release of lysosomal granules and oxygen products from neutrophils²⁴ and macrophages, and are also thought to attract neutrophils and monocytes to the wound;²⁵ the latter develop into macrophages, which characterize the late inflammatory phase.

Neutrophils (polymorphonuclear leukocytes) and monocytes are both attracted to the wound site at the same time,²⁶ but neutrophils arrive initially in greater numbers, partly due to their greater abundance in the blood, and thus the early phase of inflammation is classified as being neutrophil-rich. They are attracted by a variety of general leukocyte chemotactic factors,⁵ including fibrinopeptides,²⁷ fibrin lysis products,^{28, 29} C5a,²⁵ LT B₄,³⁰ formyl methionyl peptides,³¹ platelet-activating

factor (PAF),³² tumour necrosis factor alpha (TNF α),³³ PF4¹⁵ and PDGF.³⁴ Members of the α -chemokine family of low molecular weight chemotactic factors are generally specific for neutrophils³⁵ and are exemplified by IL-8, growth-related protein and melanoma growth stimulating activity (MGSA).³⁶ In contrast, the monocyte influx is further stimulated by representatives of the β -chemokine family,³⁵ including factors such as monocyte chemoattractant protein-1 (MCP 1)³⁷ and macrophage inflammatory protein-1 α (MIP-1 α).³⁸ Other monocyte chemotactic factors implicated as attractants of this cell type *in vivo* are platelet-derived endothelial cell growth factor (PD-ECGF),³⁹ thrombin,⁴⁰ TGF β ³⁴ and fragments of collagen,⁴¹ elastin,^{42, 43} and fibronectin.⁴⁴

The main function of the neutrophils which infiltrate the wound bed is the phagocytosis of pathogenic bacteria and debris.⁴⁵ The inflammatory environment stimulates the release of toxic reactive oxygen intermediates from the neutrophil granules, destroying the contaminating bacteria,⁴⁶ but also having the capacity to cause significant damage to the surrounding tissues.⁴⁷ However, the presence of neutrophils in the wound environment is not critical as neutropenia does not adversely interfere with wound healing.⁴⁸

Neutrophil infiltration ceases within a few days of injury in the absence of bacterial infection, but is lengthened in contaminated wounds.⁴⁹ Once bacterial contamination has been controlled, effete neutrophils are entrapped within the clot or phagocytosed by tissue macrophages or fibroblasts⁵⁰ and neutrophil infiltration ceases, indicating the end of the early inflammatory phase of repair.

LATE INFLAMMATION

The transition from the early to the late inflammatory phase is made as the neutrophil infiltrate resolves and the accumulation of macrophages continues. Monocytes rapidly differentiate into macrophages after migrating from the vasculature into the wound site. The factors responsible for this differentiation have not been fully identified, but may include the presence of insoluble fibronectin,⁵¹ low oxygen tension,⁵² chemotactic agents⁵³ and the presence of bacterial lipopolysaccharides and interferons.³⁵ Wound macrophages eliminate deleterious materials, e.g. microorganisms and wound debris, by phagocytosis,⁵⁴ generate chemotactic factors, which are responsible for the recruitment of additional inflammatory cells, and release collagenases which are degrading enzymes that lyse necrotic material.^{55, 56} Wound macrophages are also thought to synthesize and release growth and regulatory factors, critical to the coordination of granulation tissue formation^{57, 58} including PDGF,⁵⁹ TGF β ,⁶⁰ TGF α ,⁶¹ fibroblast growth factor (FGF)⁶² and interleukin (IL)-1.⁶³ Leibovich and Ross⁶⁴ researched the role of macrophages in the repair of guinea-pig wounds, and found that macrophage deletion caused severe lack of

wound debridement and a delay in fibroblast recruitment and proliferation, and in matrix biosynthesis. This suggests that the growth factors and chemotactic factors released by the macrophage are important in the initiation and propagation of granulation tissue and that the macrophage plays a vital role in the transition from the inflammatory phase to the proliferative phase of wound repair.^{35, 65}

New tissue formation (proliferation)

Overlapping with and also following the inflammatory response approximately five days post-injury,⁶⁶ there is a proliferation at, and migration into, the wound site of those cells that are responsible for the remainder of the repair process, for the ensuing 10–14 days.⁶⁷ This dense population of macrophages, fibroblasts and endothelial cells, etc., embedded in a loose matrix of collagen types I and III, fibrin, fibronectin and proteoglycans rich in hyaluronic acid, is referred to as granulation tissue. The term ‘granulation tissue’ is derived from the granular surface appearance of the loops of newly formed capillaries in the tissue, before their coverage by epidermal cells (Figure 8.3).

The macrophages, fibroblasts and endothelial cells migrate into the wound bed (Figure 8.4) as a mutually dependent unit, known as the ‘wound module’.⁶⁸

The macrophage as described above, releases chemotactic and growth factors, which attract fibroblasts and endothelial cells into the wound. The fibroblasts respond to these stimuli by constructing a new ECM, through which the macrophages,⁶⁹ blood vessels⁷⁰ and fibroblasts themselves⁷¹ can migrate. The endothelial cells respond by bud formation, creating the neovasculature which supplies nutrients and oxygen to the wound, enabling the metabolic demands of macrophage and fibroblast in-growth to be satisfied.

Figure 8.3 A granulating venous leg ulcer. Image provided by TVU.

During cutaneous wound repair, the proliferative phase is manifest by re-epithelialization and granulation tissue formation.

RE-EPITHELIALIZATION

Re-epithelialization is the reconstitution of the cells of the epidermis into an organized, keratinized, stratified squamous epithelium, which covers the wound defect and restores the barrier properties of skin, decreasing morbidity and mortality after cutaneous injury.⁵

The process occurs rapidly, beginning within hours of the initial insult to the tissue, and continuing throughout the proliferative phase of repair,⁷² with the migration of intact keratinocytes from the free edge of the cut epidermis (Figure 8.5) across the defect.⁷³ The rate of migration is dependent on the tissue oxygen tension, being highest in hyperbaric conditions, where the rate of cell movement is approximately 12–21 µm per hour⁶⁷ and

Figure 8.4 Histology section showing a typical diverse cell population during the proliferative phase of repair. Image supplied by M. Calvin.

Figure 8.5 Leg ulcer showing migrating epithelium from the wound edges. Image supplied by TVU.

on the humidity of the environment, migration occurring at a faster rate in moist conditions.⁷⁴

In partial thickness wounds, hair follicles and the ducts of sweat glands act as a source of epidermal skin cells, whereas in full thickness wounds the only source is the wound margin.

If, during migration, keratinocytes come across small foreign particles, these are removed by phagocytosis.⁷⁵ If larger particles are encountered, the keratinocytes will migrate deep to the particles, dissecting viable tissue from desiccated nonviable tissue that is later sloughed off.⁴⁴ This process is thought to involve the secretion of collagenase and plasminogen activator by the migrating cells.⁷⁶ The stimuli for the initiation of epidermal migration are not clear, but they may involve contact guidance by matrix components of the clot.

Once the process of re-epithelialization is complete and the migrating edges have united, migration ceases, the rate of epithelial proliferation falls to approximately three to four times the normal rate; the epidermal cells rapidly reassume their original morphology and function and re-establish their desmosomal, and hemidesmosomal attachments.

GRANULATION TISSUE FORMATION

The process of granulation tissue formation consists of fibroplasia and angiogenesis.

Fibroplasia

Fibroplasia may be defined as the process of fibroblast recruitment into the wound site and the ensuing synthesis and secretion of the collagenous and noncollagenous matrix. The colonization of the wound site by fibroblasts, essential for the production and organization of the major extracellular components of the granulation tissue,⁷⁷ is thought to involve both fibroblast migration and proliferation. For optimal fibroblastic activity, a mildly acidic medium is necessary, provided by accumulation of lactate from anaerobic metabolism in the wound.⁶⁷

After injury, the fibroblasts undergo an alteration of cell phenotype when they migrate into the wound bed, including sequestration of the endoplasmic reticula and Golgi apparatus at perinuclear locations, and the formation of large actin bundles orientated longitudinally in the peripheral cell cytoplasm.⁷⁸ These phenotypically altered fibroblasts have acquired the capacity for contraction and increased motility and are termed myofibroblasts.^{79, 80} It is thought these myofibroblasts originate from resting fibrocytes and fibroblasts situated in the wound margins⁸¹ and that the factors which induce this phenotypic alteration, although unknown, probably include the same growth factors^{58, 82} and chemoattractants which stimulate fibroblast migration.⁸³

Once in the wound, fibroblasts undergo proliferation, thought to be influenced by a plethora of growth factors

produced in part by activated macrophages,⁶¹ as well as the hypoxic conditions found in the centre of wounds.⁷⁴

In the wound area, the fibroblasts and myofibroblasts secrete a loose ECM, which initially contains large quantities of the glycoprotein fibronectin.⁸⁴ The fibronectin produced affects fibroblast function in wound healing in several ways, including aiding the adhesion of fibroblasts to the ECM, the stimulation of migration of fibroblasts, the provision of a support mechanism for the deposition and orientation of collagen fibrils and the mediation of wound contraction.⁷ Hyaluronic acid and collagen type III are also secreted, the peak rate of synthesis occurring five to seven days after injury.⁶⁸ Once a collagen-rich matrix is deposited in the wound, the fibroblasts are downregulated and cease collagen production, possibly under the influence of interferon gamma (IFN γ)⁸⁵ and the secreted collagen matrix itself.⁸⁶

Wound contraction

Wound contraction is the reduction of part or all of a skin defect, by centripetal movement of the surrounding undamaged skin.⁸⁷ It begins approximately seven days after injury, peaking at two weeks post-insult and reduces the need for scar tissue, by reducing the size of the wound. It progresses at a rate of 0.6–0.7 mm per day, independent of the size of the wound.⁶⁷

Wound contraction is a major form of wound closure in mobile-skinned animals such as rats, where the *panniculus carnosus* enables the skin to move easily over the underlying fascia, and therefore contraction rarely leads to loss of function of the involved tissue. In humans, however, where the skin is less mobile due to its attachment to underlying structures, contraction alone rarely closes a wound, the degree of contraction varying with the depth of the wound.⁷⁴

For optimal healing, the degree of contraction needs to be maintained in equilibrium; a diminished level of contraction leads to delayed wound closure, resulting in excess bleeding and possible infection, whereas excessive contraction may lead to tissue contracture, possibly causing deformity and dysfunction (Figure 8.6).

There are currently two main theories postulated to explain how fibroblasts may generate and transmit the force necessary to facilitate wound contraction:

1. cell contraction – myofibroblast theory;⁸⁸
2. cell traction – fibroblast theory.⁸⁹

Myofibroblast theory

This theory suggests that myofibroblast cells which have morphological characteristics of both fibroblasts and smooth muscle cells and are aligned within the wound along the lines of contraction⁵ are responsible for the process of wound contraction. The myofibroblast displays many cell-to-cell and cell-to-matrix contacts and these contacts provide a means by which cellular contraction

Figure 8.6 (a) Patient has had a skin cancer (basal cell carcinoma) removed from the side of his nose and cheek. The wound was allowed to heal by secondary intention. (b) Appearance of wound four weeks later. Note how the natural forces of wound contraction have produced a severe distortion of the eyelid (ectropion). (c) To repair the ectropion, scar was removed and a full thickness skin graft was applied to the area. Appearance one month following skin grafting. Courtesy of William Panje.

pulls collagen fibrils towards the body of the myofibroblast,⁹⁰ causing a reduction in granulation tissue area.

Fibroblast theory

This theory suggests that fibroblasts act as the agents of wound closure by exerting 'tread-like traction forces' on the ECM fibres to which they are attached; the process being analogous to the traction forces exerted by wheels on a surface.⁹¹ This theory proposes that fibroblasts neither shorten in length, nor act in a coordinated

multicellular manner, but rather that the traction forces of many individual fibroblasts are responsible for wound contraction.⁹²

Wound contraction may be brought about by a combination of both these theories. It is possible that the wound matrix is initially remodelled by the process of fibroblast traction, which is subsequently superseded by the contractile activity of myofibroblastic cells, as traction is known to proceed initially without myofibroblast cells.⁹³

Angiogenesis

Angiogenesis (the process of new blood vessel formation) occurs simultaneously with fibroplasia, commencing two to three days after injury,⁹⁴ and is a process involving phenotypic alteration, migration, proliferation and synthesis of ECM,⁷⁰ whereby capillaries bud from pre-existing functioning small venules in close proximity to the wound, and extend into the wound site.⁹⁵ Granulation tissue produced during the proliferative phase of repair, while only transient, is metabolically very active and consequently requires a profuse blood supply. Without such a supply, invasion of the wound bed by macrophages and fibroblasts would cease, partly through lack of oxygen and nutrients.

The process of angiogenesis during dermal repair is thought to result from the actions of various angiogenic stimuli, generated during injury or as a consequence of the initiation of the repair process.⁵ Activated macrophages release potent angiogenic stimuli⁵⁸ including FGF which is strongly mitogenic for endothelial cells and stimulates angiogenesis both *in vitro* and *in vivo*,⁷ TNF α ⁹⁶ and IL-8.⁹⁷ Endothelial cell proliferation is also stimulated by lactic acid,⁹⁸ biogenic amines⁹⁹ and low oxygen tension,¹⁰⁰ all of which are generated in the relatively hypoxic wound environment. Various platelet-derived substances, such as PD-ECGF, have been shown to promote endothelial cell migration and proliferation,¹⁰¹ and TGF β also influences the migration of endothelial cells.^{57,102} Other platelet-derived substances which indirectly affect angiogenesis by recruiting monocytes or other cells to produce angiogenic factors¹⁰³ include PAF,³² PDGF¹⁰⁴ and PF4.¹⁵ Heparin¹⁰⁵ and fibronectin⁷ are also thought to be involved in the process of angiogenic stimulation.

The pericyte–endothelial cell interaction may also play an important role in the formation of new blood vessels, since pericytes have been shown to regulate endothelial proliferation and differentiation, function as progenitor cells and synthesize and release structural constituents of the basement membrane and extracellular matrix.¹⁰⁶

Angiogenesis is a limited process, but the mechanisms regulating it are not clear. It is thought that the loss of angiogenic stimuli may result in its downregulation. Pericytes may reduce the angiogenic response by inhibiting the growth of adjacent endothelial cells.^{106,107} Other events that may act as a brake to the angiogenic process include the cessation of chemotactic and mitogenic factor generation as the inflammatory response wanes, the inactivation of FGF by heparin-like molecules and a return to the normal, nonmacrophage-activating oxygen tension, thus reducing the availability of angiogenic factors produced by macrophages.¹⁰⁰

Matrix formation and remodelling

Remodelling of the immature tissue matrix commences simultaneously with granulation tissue formation,

although for clarity it is normally regarded as forming the third and final phase of wound healing due to its continuation for many months or years after granulation tissue has been resolved.⁴⁴ During this phase, the highly cellular and highly vascular granulation tissue is gradually replaced and remodelled forming scar tissue, which is less cellular and less vascular than the granulation tissue. This decrease in cellularity may be due to the migration of the cells out of the wound site or by programmed cell death (apoptosis).

The scar tissue of the wound remains functionally inferior to the original tissue and serves as a diffusional barrier to nutrients and oxygen.¹⁰⁸ It also never regains its original tensile strength, only reaching 70–80 percent of that of normal skin.¹⁰⁹ Work carried out in rats by Pickett *et al.*¹¹⁰ demonstrates that the tensile strength of wounds closed under tension exceeds that of tensionless wounds from seven days post-wounding.

The composition and structure of the granulation tissue ECM is constantly changing from the time of its first deposition.¹¹¹ The ECM is first deposited at the wound margins at the onset of granulation tissue development, but is later laid down more centrally as the granulation tissue fills the wound space. Therefore, the characteristics of the granulation tissue ECM at a given time within the wound, depend on both the time elapsed since tissue injury and the location within the wound, with regard to its distance from the wound margin.⁸⁴

As the matrix matures, both hyaluronic acid and fibronectin, which play an important role in cellular ingrowth to the wound site, are reduced. There is an accumulation of type I collagen bundles and an alteration in their intermolecular cross-links,¹¹² which provide increasing tensile strength to the residual scar. Proteoglycans are also deposited and these increase the wound's resilience to deformation.

The increase in tensile strength is caused not only by the increase in collagen deposition, but also by the remodelling and realignment of the collagen into larger fibrillar bundles,¹¹³ and an alteration of intermolecular cross-links.¹¹² During remodelling, the fibres become less randomly orientated. This may be due to the mechanical forces exerted on the scar during normal usage, improving its mechanical function so it resembles uninjured dermis more closely.⁴⁵

The remodelling of collagen is dependent upon the interplay of continued collagen synthesis and collagen degradation.⁴⁴ The degradation is controlled by a variety of collagenase enzymes synthesized by granulocytes, macrophages, epidermal cells and fibroblasts.¹¹⁴

The process of collagen remodelling continues for many months or years in the healing wound,⁵ but the tensile strength of the scar tissue, a functional assessment of collagen, can only reach 70–80 percent of its pre-injury strength.⁷⁴ The mechanical and cosmetic properties of the scar never reach those of the uninjured skin.

REPAIR OF BONE TISSUE

The repair process of bone tissue is essentially the same as that described for soft tissue, with an added osteogenic component. In summary, immediately after injury haemorrhage occurs. The clot is formed, and the acute inflammatory phase of repair begins. As with soft tissues, mast cells, neutrophils and macrophages move into the area releasing factors, which stimulate tissue repair. Wound debris is removed by the action of macrophages and osteoclasts and a gradual formation of granulation tissue occurs to replace the clot. This is completed within several days depending upon the nature and severity of the injury.

Osteoblasts, whether derived from osteocytes, fibroblasts or a number of other sources, are activated. This activation is due to the combined action of a number of factors, including mast-cell factors, anoxic conditions and bone-morphogenic substances. Chondroblasts may also become active under certain conditions, especially when oxygen levels are low. Small groups of cartilaginous cells appear within the new matrix, mainly in the region of the periosteum. Calcium is deposited by the osteoblasts both directly in the tissue matrix and in the islands of cartilage. The fracture site at this stage of repair is referred to as the soft callus, due to its flexible nature.

Following this stage, both subperiosteal and endochondral ossification continues. After approximately two months, the bone ends become united to form the hard callus. Remodelling continues in the callus to form mature lamellar bone, involving the action of both osteoblasts and osteoclasts. The remodelling restores the marrow cavity, and at the same time the contour of the bone becomes smooth. Much of this remodelling is determined by the normal external forces to which it is submitted.

Conclusion

Wound healing involves the integrated action of a number of cell types, the ECM and soluble mediators. Clinically, our aim is to restore the integrity and function of the tissue as rapidly as possible after injury. The three overlapping phases of wound healing have been detailed. The inflammatory phase is marked by platelet accumulation, coagulation and leukocyte migration into the wound bed. The proliferative phase is characterized by (1) re-epithelialization restoring the cutaneous barrier; (2) angiogenesis, the neovasculature supplying much of the nutrition required for healing during this phase; (3) fibroplasia, forming the collagenous and noncollagenous matrix for the dermal component of the wound; and (4) wound contraction, reducing wound size and thus the need for scar tissue. Finally, the remodelling phase takes place over a period of months, during which the dermis responds to injury with a dynamic continuation of collagen synthesis and degradation, and the once highly vascular

granulation tissue undergoes a process of devascularization as it matures into less vascular scar tissue.

HOW DO WE NOW LINK THIS BASIC KNOWLEDGE TO PRACTICE?

Diagnosis, diagnosis, diagnosis – this is the key to successful wound healing. A wrong diagnosis can result, at best, in delayed healing, at worst, amputation or death of the patient.

When a patient with a wound first presents, a number of questions should be addressed which will aid the diagnosis:

1. What is the patient's age?
2. What is the patient's nutritional status?
3. Are there any underlying chronic conditions, such as diabetes, peripheral vascular insufficiency, etc.?
4. Is the patient on any drug regime?
5. Is there any infection present?

What is the patient's age?

Ageing affects all stages of wound healing. The onset of the inflammatory phase of repair is delayed and lasts longer. Cell proliferation and metabolism decreases. The rate of capillary growth into the wound bed and mast cell numbers decrease with age. The diminished blood flow causes decreased clearance of metabolites and foreign materials, and increased tissue hypoxia which delays healing.

Wound remodelling is also affected by age due to decreased fibroblast activity. There is also a reduction in the amount of collagen organization and cross-linkage which results in decreased tensile strength.¹¹⁵

What is the patient's nutritional status?

An adequate supply of nutrients is essential for wound healing. Malnutrition or any deficiencies of nutrients, e.g. zinc, vitamin C or iron, may delay wound healing and will lead to impaired immune resistance increasing the risk of infection. Lennard-Jones¹¹⁶ highlighted the problems associated with malnutrition including loss of muscle tissue, impaired immune resistance to infection, increased risk of complications, prolonged recovery and increased length of hospital stay. These lead to not only the economical expense of prolonged hospital stay, but also the physical and emotional cost to the patient.

NUTRITIONAL ASSESSMENT

It is important for malnourished patients and those at risk of malnutrition to be identified early and referred to the dietitian for assessment.

By asking a few simple questions, nutritional problems can be highlighted and addressed on a patient's admission to hospital.

A simple tool including four questions is worth remembering:¹¹⁷

1. What is your normal weight?
2. How tall are you?
3. Have you unintentionally lost weight?
4. Have you been eating less than usual?

You may also wish to find out about activity levels; is this normal or reduced? Have there been any unusual losses such as chronic diarrhoea or vomiting?¹¹⁶

Other measurements of nutritional status include:

- serum albumin: (30–35 g/L is a possible indicator of moderate malnutrition; <30 g/L is a possible indicator of severe malnutrition);
- serum transferrin: (1.0–1.5 g/L is an indicator of moderate malnutrition; <1.0 g/L is an indicator of severe malnutrition);
- triceps skinfold thickness: (10 mm in males and <13 mm in females is an indicator of malnutrition.^{118, 119, 120, 121}

Are there any underlying chronic conditions such as diabetes, peripheral vascular insufficiency, etc.?

Diseases that cause tissue hypoxia, such as diabetes, arteriosclerosis and chronic venous insufficiency, all retard wound healing.

Figure 8.7 shows a typical example of a diabetic wound and it occurs for a multitude of reasons, e.g. impaired vascular supply leading to reduced oxygen levels, elevated glucose levels leading to reduced vitamin C transport, reduced collagen synthesis, impairment of leukocyte function, etc. The primary aim should always

© Hodder Arnold / Scott-Brown 7E

Figure 8.7 A diabetic wound. Image provided by TVU.

be to address the underlying diabetes first. This will make the problem of wound healing easier.

Is the patient on any drug regime?

Drugs that the patient may be taking include:

- antiinflammatory drugs;
- glucocorticosteroids depress the inflammatory phase of repair by inhibiting neutrophil and monocyte recruitment and by suppressing macrophage phagocytosis;
- cytotoxics;
- anticoagulants;
- immunosuppressives;
- penicillamine;
- HRT.¹²²

Is there any infection present?

Bacterial contamination of a wound delays healing. Infection can prolong the inflammatory response, which causes further tissue damage. The susceptibility of a wound to infection is increased by a number of factors: the presence of necrotic tissue, foreign particles and haematoma in the wound. Apart from causing wound complications, bacteria may spread into the bloodstream causing bacteraemia and septicaemia.

Once these questions have been answered, the wound then needs to be fully classified and assessed. Classification falls under three main headings:

1. wound closure;
2. cause of the wound;
3. stage of healing.

It is important to be as accurate as possible with this classification because the subsequent treatment of the wound varies tremendously depending upon the answers obtained.

Categorization by wound closure

One of the most common ways to assess a wound is based on the degree of tissue loss, which in turn dictates the method of closure. The two basic types of wound closure are termed 'primary intention' and 'secondary intention', described under Healing by first intention and Healing by second intention.

In primary intention wounds where tissue loss has been minimal (see under Healing by first intention), it is possible to have the edges opposed and secured (usually with sutures, but possibly with clips, glue or adhesive strips).

In secondary intention wounds where tissue loss has been so great (see under Healing by second intention), it is not possible to bring the edges of the wound together and sutured in the same way as in the primary intention wounds. They have to heal by contraction and by filling up with granulation tissue. Examples of these are leg ulcers and pressure sores. The resulting scar from this type of healing is generally more pronounced than that produced by primary intention healing.

Categorization by the cause of the wound

ACUTE OR CHRONIC?

By categorizing wounds according to the way in which they occurred, they fit into a number of different groups. The two basic groups are termed 'acute' and 'chronic' wounds. Acute wounds are a result of trauma, e.g. thermal, mechanical, chemical, radiation, etc. In most acute wounds, when the cause of the injury is removed the wound tends to heal. In chronic wounds there tends to be an underlying pathology in the individual, e.g. diabetes, venous insufficiency, malignancy, which causes the wound to persist even when the original cause is removed. This is because the factors which are necessary for successful healing may be absent in the physiology of these individuals, e.g. cytokines, patent blood supply, etc.

ACUTE WOUNDS

There are a number of general categories of acute wounds:

- thermal wounds;
- postoperative wounds;
- mechanical injuries.

THERMAL WOUNDS

These wounds are caused by extremes of heat and cold and also radiation. Irradiation, which is frequently used to treat head and neck cancer, causes irreparable damage to the skin's microvasculature. As a consequence of reduced blood supply, resulting from irradiation, wounds heal poorly and are much more susceptible to infection than are nonirradiated tissue beds (**Figure 8.8**).

The major problem associated with this type of wound is in the assessment of the true extent of the injury. Burns are the most common type of this injury. Burns can be divided into three groups according to their severity.

1. **First degree:** This type of wound affects the upper layer of the epidermis and no intervention is generally needed. An example of this is sunburn.
2. **Second degree:** This type of burn generally results in blistering. It is advised that to reduce the chances of infection the blister should remain

© Hodder Arnold / Scott-Brown 7E

Figure 8.8 Patient had radiation treatment for acne 25 years previous to this photograph. Her lips are now infiltrated with invasive cancer. Note the extensive scarring resulting from the previous radiation. Courtesy William Panje.

intact. As with first-degree burns, minimal intervention is needed.

3. **Third degree:** This type of burn is the most serious and results in large areas of tissue necrosis. To allow new tissue to develop the necrotic tissue must be debrided, otherwise any intervention, such as grafting, will fail.

There have been many attempts to develop a tool to accurately measure the depth of second-degree burns. This measurement is critical in determining whether to treat the burn surgically or conservatively. Once debridement has been carried out, a range of grafting techniques are available depending upon individual circumstances:

- **autologous:** graft from one part of the body to another and also grafts which are grown in tissue culture from the patients own cells;
- **homologous:** graft from a donor to recipient of the same species, e.g. human to human;
- **heterologous:** donor and recipient are from different species, e.g. pig to human;
- **alloplastic:** temporary graft made from a foreign material such as plastic.

POSTOPERATIVE WOUNDS

There are numerous types of postoperative wounds, the most common are:

- incisions;
- skin biopsy;
- split thickness skin flaps;
- amputation.

Incisions

These wounds are typically made by a scalpel and will extend through the full thickness of the skin into the underlying tissues (see under Healing by first intention). Healing will be by primary intention.

Skin biopsy

This wound generally involves the surgical removal of a small area of full thickness skin for the purpose of histological examination of suspect tissue. Healing will normally be by primary intention.

Split thickness skin graft

This type of wound extends through the epidermis into the superficial layers of the dermis (papillary layer). This is not a full thickness wound and is equivalent to an abrasion resulting in minimal scarring.

Amputation

These wounds are caused by the surgical removal of a limb in order to save the individual. The wounds will generally heal by a mixture of primary and secondary intention depending upon the degree of tissue loss and the ability to graft a tissue flap to the injury site.

MECHANICAL INJURIES

These wounds are the most common and we have all experienced some form of mechanical injury at some point in our lives. Fortunately for most of us they are minor wounds and are not life threatening. However, some people face more serious mechanical injuries, which can at best disable and at worst kill. In addition to the initial mechanical injury there is also the possibility of infection, which can sometimes make a nonlife-threatening trauma become life threatening. Common examples of trauma wounds are:

- abrasions;
- blisters;
- bites;
- bruises;
- cuts;
- stabs;
- gunshots.

CHRONIC WOUNDS

The three most common types of chronic wound are:

1. diabetic wounds;
2. pressure ulcers;
3. leg ulcers.

Diabetic wounds

Diabetic wounds occur for a multitude of reasons, which have been previously discussed under Are there any underlying chronic conditions such as diabetes,

● Hodder Arnold / Scott Brown 7E

Figure 8.9 Typical pressure ulcers of the heels. Image provided by TVU.

peripheral vascular insufficiency, etc.? The primary aim should always be to address the underlying diabetes first, otherwise healing will be delayed.

Pressure ulcers

These wounds are typically caused by the action of pressure and shear forces on an already compromised tissue, which is overlying a bony prominence (**Figure 8.9**). Pressure ulcers tend to be divided into four groups depending upon the depth of the wound (**Figure 8.10**).

1. **Stage I:** This is a nonblanchable erythema of intact skin.
2. **Stage II:** This is defined as partial thickness skin loss involving the epidermis and the upper layer of the dermis (papillary zone).
3. **Stage III:** This is defined as a full thickness skin loss and extends into the underlying subcutaneous fat.
4. **Stage IV:** This is defined as a full thickness skin loss with extensive damage through the subcutaneous fat into the underlying muscle, bone and supporting tissue.

Leg ulcers

Legs ulcers are usually caused by deterioration in the arterial and/or the venous supply in the lower limb.

Venous leg ulcers

This type of ulcer accounts for approximately 70 percent of all leg ulcers. These wounds result because of a severe venous insufficiency in the lower limb. This results in reduced blood supply to and drainage from the tissues of this region. Once compromised in this way the tissues are easily damaged by the slightest injury, leading to ulceration.

Arterial leg ulcers

Approximately 10 percent of leg ulcers are arterial. The cause is due to blockage of an artery, which leads to a

© Hodder Arnold / Scott-Brown 7E

Figure 8.10 Pressure ulcer: (a) stage I; (b) stage II; (c) stage III; (d) stage IV. Artwork supplied courtesy of Hill-Rom®.

decrease in the blood flow to the tissues. This leads to a decrease in oxygen and nutrients to the area and so an ulcer is formed. The main cause of arterial blockage is smoking.

Categorization by stage of healing

A third way to categorize a wound is according to the type of tissue present within it. The type of tissue present will be directly related to the stage the wound is at in the healing process.

As discussed at the start of this chapter, there are three basic stages or phases of healing.

INFLAMMATION

Inflammation is characterized clinically by the common signs of heat, pain, swelling and redness and, microscopically, by the degranulation of mast cells and the presence of phagocytes, such as macrophages, in the wound (see under Inflammation above).

PROLIFERATION

Proliferation is the stage of new vessel and tissue growth (see under New tissue formation (proliferation)). It is characterized, clinically, by granulation and epithelial tissue and, microscopically, by the presence of fibroblasts (from approximately day 2 onwards), the synthesis of collagen, angiogenesis (the formation of new vessels) and the presence of epithelial cells.

REMODELLING

Remodelling is the stage where the collagen fibres that have been randomly laid down are reorganized (see under Matrix formation and remodelling). This may take several years to complete.

From these stages of healing, five different tissue types can emerge:

1. granulation;
2. epithelial;

3. slough;
4. necrotic;
5. infected.

Granulation tissue

This tissue can be recognized by its red, moist, shiny and granular appearance as shown in **Figure 8.3**. A biopsy of this tissue would reveal an abundance of blood capillaries, macrophages and fibroblasts.

Epithelial tissue

As the wound heals and fills with granulation tissue, the new epidermis will grow across it from the edges of the wound moving towards the centre of it. The appearance of the epithelial tissue is pinky/white (see **Figure 8.5**). Growth of epithelial tissue can also occur from hair follicles, sebaceous and sweat glands in the wound tissue itself. This means that source of growth of the new epidermis is not just restricted to the periphery of the wound, but can occur throughout the entire wound. This can give rise to islands of epithelial tissue often seen in the middle of expanses of granulation tissue.

Slough

This is seen as a yellow or white deposit in the wound (**Figure 8.11**). This deposit may be runny or fibrous in nature and is common in chronic and infected wounds. Epithelial tissue and tendons are often mistaken for slough, so care is needed when deciding whether to debride the tissue or not.

Necrotic tissue

This tissue is black or black/brown in colour with a leathery texture. This is dead tissue and has to be debrided before healing can commence.

Infected tissue

This tissue can be identified by a number of classical signs:

- erythema;
- presence of pus;
- excess exudate;
- odour;

© Hodder Arnold / Scott-Brown

Figure 8.11 Wound covered with slough. Image provided by TVU.

Figure 8.12 A tissue sample being tested for tensile strength using an Instron machine. Picture courtesy of M. Calvin.

- change in pain;
- pyrexia;
- delayed healing;
- friable granulation tissue;
- pocketing at base of wound;
- bridging of soft tissue and epithelium;
- wound breakdown.

IDENTIFYING INFECTION

Traditionally a swab is taken of the wound surface and sent to the laboratory for identification. 10^5 bacteria per gram has been the recognized point at which the bacteria are at a level which will inhibit wound healing. Therefore, this has been the level at which a wound is officially classified as being infected.

It must be understood that this level of bacteria in a wound may not necessarily be detrimental to all individuals. Some people can have this level of bacteria in their wound and will still heal successfully without delay or adverse reaction. Other individuals may suffer adverse reactions to this level of bacteria.

So interpreting what exactly your swab results mean can be very much an individual decision. Swabs provide some information about the type of bacteria present, but the important point is to identify whether the bacteria is causing delayed healing.

WOUND ASSESSMENT

Numerous techniques exist for the assessment of wounds. They can be divided into two basic categories: invasive or noninvasive.

Invasive

These techniques yield quantitative results and involve biopsy of the wound.

- **Histology** gives an indication of the number and type of cells present and therefore a good estimate on the stage of healing (see **Figure 8.4**).¹²³
- **Biochemical analysis** gives an indication of what matrix materials are present, e.g. collagen type.¹²⁴
- **Tensile strength** gives an indication of wound strength (**Figure 8.12**).¹²⁵
- **Angiography** gives an indication of wound vascularity.¹²⁶

Noninvasive

Whilst less quantitative than the invasive methods, these techniques are more acceptable to patients as they do not involve biopsy.

Wound area

Acetate or polythene film is placed over the wound and the outline traced using a permanent marker pen. The wound surface area is measured by computer or by placing tracing on to graph paper and counting the squares. Inaccuracies can be found when trying to define the wound edges. An alternative to tracing is photography, where the wound is photographed and measurements made from the image. A reference scale must always be included in the photograph (**Figure 8.13**).

Wound depth

A device known as the Kundin gauge¹²⁷ can be used to measure length, width and depth of a wound from which area and volume are calculated. Be aware that the method often underestimates area and volume; however, it is easy to use and is, disposable, objective and inexpensive.

Wound volume

By making moulds of the wound (silicone rubber, silastic foam, alginates, hydrocolloid gel), the wound volume can be estimated by placing the acquired mould into a beaker

Figure 8.13 A wound with calibration reference present.
Picture courtesy TVU.

of water and measuring the displaced water volume.¹²⁸ Other methods include covering the wound with a film and injecting saline into the wound. The amount of saline it takes to fill the cavity up to the film can then be measured; however, this is not satisfactory for superficial wounds.¹²⁹

Stereoscopic photography can also be used to estimate volume.¹³⁰

Thermal imaging

Infrared radiation (heat) emitted from the skin and wound is visualized using this technique. The more vascularized an area is the more heat is emitted. Interpretation of results can be difficult as the wound temperature can be subject to variations in factors other than vascularization, e.g. room temperature, underlying infection.

High-frequency diagnostic ultrasound

This relatively new noninvasive method allows the clinician a high resolution view deep into the skin and wound bed to assess the quality of the tissue.^{131, 132, 133, 134, 135, 136}

This is a simple procedure and can even be carried out without the need to remove certain wound dressings. Because you can view under the surface of the skin, it is possible in certain cases to monitor changes in a wound even before they become clinically evident and therefore recognize whether the wound is deteriorating or improving. This ability can lead to considerable savings in treatment times. Wound depth can also be calculated using this technique, e.g. in burn injuries. This is a rapid, sensitive and repeatable method of quantifying wound healing.

Assessment of blood flow using Doppler ultrasonography

Combined with a full physical examination and clinical history, this assessment gives an indication of arterial blood flow to the lower limb.

Rationale for wound dressing choice

Once the wound has been correctly identified and assessed according to the above criteria, a choice has to be made as to which treatment or dressing will be applied to produce the best healing possible. The following is a guideline to aid the clinician in his/her choice:

DISCOLOURED, UNBROKEN SKIN

Dry skin

Simple, bland ointments, e.g. yellow/white soft paraffin. Avoid perfume/scented emollients. Nonsting barrier preparations, e.g. Cavilon and Supraskin – also for prevention and treatment of maceration or excoriation to the periwound area.

Skin conditions associated with wounds

Paste bandages, prescribed steroids may be necessary for eczema.

Skin subject to pressure or trauma

Primarily appropriate pressure relief, but foam dressings, low adherent dressings and vapour permeable films may occasionally be appropriate.

EPITHELIAZING WOUNDS

Dressing choice depends on the level of exudate: vapour permeable films, silicone membranes, low/nonadherent dressings, paraffin tulle, hydrocolloids, hydrogels, alginates, foams.

FLAT DRY WOUNDS

Choice of dressing for flat, dry wounds include low adherent dressings, vapour permeable films, membrane dressings and thin hydrocolloids.

FLAT MOIST WOUNDS

Choice of dressing for flat, moist wounds include low adherent dressings, nonmedicated tulle, vapour permeable films, membranes, hydrocolloids, hydrogels, foams, alginates and hydrofibre.

GRANULATING WOUNDS

Dressing choice depends on the level of exudate and depth of wound. Deep wounds that extend into the dermis will need to be packed gently with a suitable dressing. Dressings include hydrocolloids, alginates, foams, hydrogels and hydrofibre.

- **Exuding wounds**

- Light–medium exudate:
 - foams;
 - alginates;
 - hydrocolloids, transparent or thin dressings;
 - hydrogel, sheets or gels;
 - hydroactives, transparent or thin dressings;
 - hydrofibre.
- Medium–heavy exudate:
 - alginates;
 - hydrocolloids;
 - hydrofibre;
 - foams, extra or plus foams, i.e. those with greater absorbency;
 - hydroactives;
 - vacuum-assisted closure therapy (VAC).
- Heavy exudate:
 - alginates;
 - hydrofibre;
 - foams, extra or plus foams, i.e. those with greater absorbency;
 - VAC therapy.

- **Cavity wounds**

- Hydrofibre (Aquacel);
- foams, cavity wound dressings, Cavicare;
- alginate, rope, ribbon, cavity dressing;
- hydroactives, cavity dressing;
- hydrogels;
- hydrocolloid paste;
- sugar pastes, thick and thin;
- Cadexmer iodine, infected or critically colonized cavities;
- iodine ointment, infected or critically colonized cavities;
- VAC therapy.

- **Sloughy wounds:** Modern products will remove slough and absorb exudate.

- Hydrofibre;
- hydrogels;
- hydrocolloids;
- alginates;
- sugar pastes;
- mechanical debridement;
- scalpel (with or without local/general anaesthetic);
- biosurgical debridement using larvae, e.g. Larv E;
- enzymatic debridement, e.g. Varidase;
- miscellaneous: whirlpool, hydrotherapy, high-pressure irrigation.

- **Infected wounds**

- General infection control measures, e.g. hand washing;
- systemic antibiotics, depending on local/systemic signs of infection;
- topical antimicrobials.

- **Necrotic wounds**

- Hydrocolloids;
- hydrogels (ensure they do not macerate surrounding skin);
- mechanical/surgical debridement;
- biosurgical debridement using larvae, e.g. Larv E;
- enzymatic debridement, e.g. Varidase.

- **Malodorous wounds**

- Reduce levels of bacterial colonization;
- activated charcoal dressings;
- sugar paste (thick and thin);
- metronidazole gels: use judiciously, e.g. for fungating, malodorous tumours.

- **Malignant/fungating wounds**

- Control bleeding (topical Adrenalin or Leutral, Surgicel);
- assess pain and analgesia requirements;
- treat or mask odour;
- debride wounds;
- reduce volume of exudate;
- reduce inflammation, e.g. by removing sensitizing agents;
- care for surrounding skin;
- improve cosmetic appearance, e.g. reduce tumour bulk, avoid bulk dressings;
- enable patient to cope with altered body image.

- **Oedematous wounds**

- Compression bandages;
- exercise;
- elevation of limb.

Over/hypergranulation tissue

Over/hypergranulation tissue occurs in many types of wounds when the inflammatory phase of healing is prolonged unnecessarily. Ideally any treatment should not further exacerbate the inflammatory reaction and should be nontraumatic.

There is no consensus as to the correct treatment, but the most frequently used methods are:

- change from an occlusive to a nonocclusive dressing, such as Lyofoam;
- application of light pressure to the wound bed by the addition of supplementary padding or bandages;
- short-term topical application of corticosteroid, e.g. Terracortril (tetracycline and hydrocortisone ointment) or Daktacort (miconazole and hydrocortisone cream);
- allowing the overgranulation to resolve itself without treatment.

CARE OF THE SURROUNDING SKIN

- Paste bandages;
- 50 percent white soft paraffin and 50 percent liquid paraffin for hydration of dry skin conditions;

- oily cream or 50:50 plus 2 percent salicylic acid for extremely dry scaly patches;
- diprobase for hydration.

SPECIFIC WOUNDS

A precise diagnosis and assessment of circulation is required.

- **Venous ulcers**
 - Treat tissue type in ulcer bed;
 - compression bandages, elevation, exercise;
 - paste bandages to treat skin conditions;
 - judicious use of Elocon topical steroid for eczema.
- **Arterial ulcers**
 - Treat tissue type in ulcer bed;
 - paste bandages to treat skin conditions, exercise;
 - compression bandages are contraindicated.
- **Mixed venous and arterial ulcers**
 - Treat as with arterial ulcers except that light compression may also be indicated.
- **Pressure ulcers**
 - Relief of pressure;
 - appropriate dressings for tissue type.
- **Burns and scalds**
 - Cold running water (10–15 minutes);
 - cling film prior to assessment of depth; flamazine often applied as an antimicrobial, but only after assessment;
 - emollient for hydration once healed.
- **Superficial burns**
 - Semipermeable films;
 - hydrocolloids;
 - Aquacel[®];
 - Mepitel[™];
 - foams.
- **Dermal burns**
 - Flamazine[®];
 - Mepitel;
 - alginates;
 - Aquacel;
 - TransCyte[®].
- **Full thickness burns**
 - Assess at specialist centre;
 - Flamazine[®];
 - Mepitel[™];
 - hydrogels.

Diabetic ulcers

Diabetic ulcers require specialist care. There is evidence of effectiveness for the following prevention:

- identification of those at high risk, referral to foot care clinics, which offer education, podiatry and footwear;
- therapeutic shoes with custom-moulded insoles.

Dermatitis artefacta

Consider this in the differential diagnosis of a wound that fails to heal.

Care of haematoma

Skilled surgical techniques can prevent haematoma formation, but excess bleeding may arise from a tense haematoma beneath a suture line. The resulting dead space can act as a focus for infection, as well as weakening the suture line and delaying normal healing.

In severe cases, the suture line may have to be reopened and the haematoma surgically evacuated. Often one or two sutures or clips can be removed to allow the haematoma to drain, but occasionally complete dehiscence of the skin layers occurs.

An open wound with a visible haematoma can be cleaned out quickly and atraumatically with either hydrogen peroxide (3 percent) solution diluted with normal saline or an enzymatic debriding agent such as Varidase, which contains streptokinase and streptodornase. Once clean, the edges can be reapposed or more commonly, left to heal by secondary intention.

Care of suture lines

The tissue bonds together after 48 hours and forms a barrier against bacteria. Wound edges are held together with sutures, staples, clips or glue and these remain in place while the scar line epithelializes and regains tensile strength.

Dressings applied after suturing do not need to be removed unless they are stained by discharge or there are clinical signs of infection.

Although technically the sutured wound has closed after 48 hours, a dressing is no longer needed over the suture line; however, a dressing prevents sutures catching on clothing and provides a cosmetic covering.

In order to prevent blister formation under adhesive-bordered, low adherent dressings, avoid application of dressings under tension and allow for swelling oedema of the surrounding tissue.

SUMMARY

The most important step in healing a wound is to diagnose the wound type accurately. This is particularly important in chronic wounds where the underlying pathology has to be addressed before prescribing a wound healing therapy. It should also be remembered that you are not merely treating a wound but the whole person. It is important to establish whether a patient is able to comply with treatment regimes once they are out of your care or will they need assistance. If assistance is needed, does the patient have relatives or friends at home willing and able to provide the necessary support or do they need this to be provided?

With the correct diagnosis and treatment regime, most wounds will heal in a straightforward manner.

KEY POINTS

- Wound healing subdivided into healing by primary and by secondary intention.
- Healing by first intention occurs in clean well-perfused wounds with minimal tissue destruction.
- Healing involves:
 - rapid epithelial proliferation within 24 hours;
 - minimal granulation tissue;
 - small scar.
- Healing by second intention occurs in:
 - gaping wounds with lacerated edges;
 - large defects that cannot be covered by grafting;
 - extensive trophic disturbances, such as leg ulcers;
 - highly suppurative wounds;
 - wounds interspersed with foreign bodies;
 - infected wounds that have undergone primary closure;
 - wounds that heal better cosmetically as a result of contraction, e.g. fingertip injuries.
- Healing by second intention involves:
 - slow epithelial migration due to increased distance cells must travel;
 - more granulation tissue formation to fill the wound from the base;
 - wound contraction resulting in tissue distortion and extensive unsatisfactory scars often with impairment of function (repair).
- Wound repair can arbitrarily be divided into three phases:
 1. inflammation including early and late phases;
 2. new tissue formation (proliferation);
 3. matrix formation and remodelling.
- Inflammation can be defined as an essential localized protective tissue response elicited by injury or destruction of tissues which serves to destroy wall off both the injurious agent and the injured tissues.
- Early acute inflammation has two important components.
 1. Clot formation results in the cessation of haemorrhage and provides a provisional fibrin matrix for cell migration. Platelet induced mediators (PDGF, PF4, TGF α , TGF β) vital to this process, modulate vascular tone and permeability and stimulate synthesis of extracellular matrix components. Blood clotting also activates complement cascades via Hagemann factor producing complement-derived anaphylotoxins which together with bradikinin increase vascular permeability to produce extravascular clot.
 - Anaphylotoxins stimulate release of vasoactive mediators from mast cells and attract neutrophils and monocytes into the wound.
- 2. Neutrophils in the early neutrophil-rich phase of inflammation are attracted by a variety of chemotactic mediators including both general leukocyte and neutrophil-specific chemotactic factors. Their main function is the phagocytosis of bacteria and debris, although their role is not critical. In clean wounds, neutrophil infiltration ceases within a few days but persists in the presence of bacterial infection. Eventually, they are phagocytosed by macrophages or fibroblasts.
- Late inflammation is characterized by the accumulation of monocytes which rapidly differentiate into macrophages. Wound macrophages:
 - eliminate deleterious materials, e.g. microorganisms and wound debris by phagocytosis;
 - generate chemotactic factors responsible for the recruitment of additional inflammatory cells;
 - release collagenases that lyse necrotic material;
 - synthesize and release growth and regulatory factors critical to the coordination of granulation tissue formation.
- New tissue formation (proliferation day 5–14). This phase is characterized by granulation tissue consisting of macrophages, fibroblasts and endothelial cells embedded in a loose matrix of collagen, fibrin, fibronectin and proteoglycans rich in hyaluronic acid.
- Re-epithelialization is the reconstitution of the cells of the epidermis into an organized stratified squamous epithelium which covers the wound defect and restores the barrier properties of skin. In partial thickness wounds, hair follicles and ducts of sweat glands act as a source of epidermal skin cells, whereas in full thickness wounds the only source is the wound margin.
- Formation of granulation tissue consists of three phases.
 1. Fibroplasia defined as the process of fibroblast recruitment into the wound site and the ensuing synthesis and secretion of collagenous and noncollagenous matrix.

Fibroblast migration and proliferation necessary for granulation tissue formation and this occurs best in a mildly acidic medium provided by the accumulation of lactate from anaerobic metabolism;

2. Wound contraction (day 7–14) is the reduction of part or all of the skin defect by centripetal movement of the surrounding undamaged skin. There are two main theories of how fibroblasts generate the force necessary to facilitate wound contraction: (1) myofibroblast theory suggest that fibroblasts have some smooth muscle fibres; (2) cell to cell and cell to matrix contacts act as anchorage points. Together these allow wound contraction to take place. Fibroblast theory suggests that they exert traction forces;
3. Angiogenesis: the process of new blood vessel formation occurs simultaneously with fibroplasia. Capillaries bud from preexisting small venules close to the wound and extend into it. Angiogenic stimulants are released from macrophages, but their control is as yet poorly understood.
- Matrix formation and remodelling: During this phase the highly cellular and vascular granulation tissue is replaced by much less cellular and vascular scar tissue. This starts simultaneously with granulation tissue formation and can go on for months or years. Scar tissue is functionally inferior to the original, acting as a diffusional barrier to nutrients and oxygen and only ever reaches 75 percent of their tensile strength of normal skin. As a wound matrix matures:
 - hyaluronic acid and fibronectin associated with cellular ingrowth reduce;
 - accumulation type 1 collagen bundles, alteration in intermolecular cross-links providing an increase in tensile strength;
 - proteoglycan deposition increases the wound's resilience to deformation;
 - collagen remodelling and realignment into larger fibrillar bundles which become less randomly orientated.

Best clinical practice

- ✓ Take relevant points in patient history:
 - age: advancing age slows all aspects of wound healing;
 - nutritional status: malnutrition (albumin <30, transferring <1 = severe malnutrition) or

deficiencies in zinc, vitamin C and iron all impair wound healing;

- underlying chronic disease, such as diabetes, arteriosclerosis and chronic venous insufficiency, all retard wound healing;
- drugs which impair wound healing include antiinflammatory drugs especially steroids, cytotoxics, anticoagulants, immunosuppressives, penicillamine and HRT;
- infection always delays wound healing.
- ✓ Classification and assessment:
 - wound closure: primary intention or secondary intention;
 - cause: acute or chronic: (1) acute: thermal wounds, postoperative wounds, mechanical injuries; (2) chronic: diabetic ulcers, pressure ulcers and leg ulcers;
 - categorization by stage of healing, i.e. by presence of inflammation, proliferation and remodelling. From these stages, five different tissue types can emerge: granulation, epithelial, slough, necrotic and infected tissue;
 - indicators of wound infection are erythema, pus, exudates, odour, change in pain, delayed healing, friable granulation tissue, pocketing at base of wound, bridging of soft tissue and epithelium, wound breakdown and wound swab counts > 105.
- ✓ Investigations used in wound assessment:
 - invasive: histology, biochemical analysis, tensile strength and angiography all of limited use because of the need to biopsy;
 - noninvasive: (1) wound area by tracing or photography; (2) wound depth using Kundin gauge can be used to estimate volume; (3) wound volume using a suitable mould or stereoscopic photography; (4) thermal imaging can give an idea of vascularity; (5) high frequency diagnostic ultrasound – can detect changes under the skin and is useful for monitoring progress; (6) Doppler ultrasonography can be used to measure blood flow.

Deficiencies in current knowledge and areas for future research

One of the biggest challenges in wound care is to give the right treatment at the right time. Wounds present an ever-changing environment; one day they may be dry and necrotic, the next, heavily exudating and infected. These different environments present different challenges to wound dressing, the former requiring a dressing that preserves or even donates moisture, the latter requiring enhanced absorptive properties. Research is needed to develop the 'ideal' wound dressing which can handle all

environments that occur during the history of a wound. Also having a dressing, which can be left *in situ* for extended periods of time, would be of enormous benefit to both patient and carer.

Our knowledge of how wounds heal and how we can enhance this healing process continues to increase each year; however, the dissemination of this knowledge from researcher to practitioner often fails. For example, there are numerous high-tech wound dressings and highly specific care protocols available, yet how often do we see inappropriate care given. In addition to this, many wounds are preventable in the first instance if only the patient had been fully assessed using the correct assessment tools. There is a definite need for systems to be developed and put into practice so that as new techniques are developed they are delivered to the practitioner.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words vasculature, vessel, physiology, skin flap and tissue transfer.

DEFINITION

A skin flap is a piece of tissue transferred from the donor site and inserted into the recipient site while maintaining a continuous attachment to the body (the pedicle). The flap may consist of skin and subcutaneous fat but could also include fascia, muscle, bone, nerve or any combination of these tissues. Although alive when transferred, the flap may subsequently die due to vascular compromise.

Microvascular flap reconstruction adheres to the same principles, except that the pedicle is created in the recipient site by microanastomoses of donor artery and vein to recipient artery and vein.

HISTORY

The origin of the term 'flap' is alleged to originate from the Dutch *Flappe* meaning as something that hung broad and loose attached only at one side.¹

Reconstructive skin flap surgery owes a great deal to the work of the Indian Ayurvedic medical practice

of nasal reconstruction. The following description is from the classical text on this surgery, the *Sushruta Samhita*:

Now I shall deal with the process of affixing an artificial nose, the leaf of a creeper, long and broad enough to fully cover the whole of the severed or clipped off part, should be gathered, and a patch of living flesh, equal in dimensions to the preceding leaf should be sliced off (from down upward) from the region of the cheek, and after scarifying it with a knife swiftly adhered to the severed nose.²

This heralds Sir Harold Gillies' third principle 'Make a plan and a pattern for this plan.'³ The English surgeon Joseph Carpue (1764–1840) is given credit for introducing the Indian forehead rhinoplasty technique into the English language text based on a letter to the editor in 1794 relating the nasal reconstruction of one bullock driver called Cowasjee. An extremely well-referenced discussion of the history of this flap reconstructive technique is given by Nichter *et al.*⁴

Greater understanding of skin flaps has occurred in both the anatomical descriptions of the blood supply and through pharmacological manipulation of the circulation.

In 1889, Manchot published on many of the distinct cutaneous vascular territories served by identified named arteries. Spalteholz⁵ described the fasciocutaneous vessels, as well as those passing through muscle, and provided the origin of the concept of the musculocutaneous blood supply to flaps. In France, Salmon⁶ added to these ideas by performing radiographs on cadaver skin following intraarterial contrast injection.

In 1963, McGregor and Morgan⁷ described how skin flaps could be considered as axial or random and therefore the length to width ratio was given an anatomical basis. Having studied intraarterial fluorescein injections in 14 patients, McGregor and Morgan deduced that an axial pattern flap could be safely raised beyond the standard dimensions of a random pattern flap of 1:1 length to width ratio. They went on to postulate that changes in pressure between one territory and an adjacent territory could create the effect of reverse flow in the adjacent axial vessels. This was further developed by Taylor and Palmer⁸ who postulated that each of the composite blocks (angiosomes) were connected by true anastomoses or reduced calibre 'choke vessels'. These choke vessels are analogous with the description by Salmon of 'retiform anastomoses' and as such are the defining limits of the vascular territories. They name the accompanying veins 'oscillating veins' in which flow could occur in either direction. In 1970, Milton⁹ reported that 'the surviving length of flaps made under similar conditions of blood supply is constant regardless of width. The only effect of decreasing width is to reduce the chance of the pedicle containing a large vessel.' As contemporary researchers have contributed increasing amounts to the anatomy of the skin circulation, larger flaps can now be raised on smaller but specifically identified vessels.

SKIN FLAP DESIGN

Skin flaps can be advanced, rotated or transposed, and initially all flaps were random pattern flaps meaning that it was a random chance whether the specific vessel was included within the pedicle and substance of the flap. The design of flaps relied on fixed length to width ratios which varies from 1:1 in the lower extremity to 4:1 in the head and neck where the blood supply was recognized to be more extensive and therefore robust. Conversely, a flap could be raised as an island based entirely on a subcutaneous pedicle.

BLOOD FLOW

Flap survival depends on blood flow through the pedicle of the flap.¹⁰ Although the fluid mechanics of blood flow

are complex, certain factors applicable to the small vessels supplying the flap are well established.

Vessel blood flow (Q) is determined by:

1. pressure difference (ΔP) between the two ends of the vessel;
2. the resistance to flow (R) produced in the vessel.

The mathematical expression of this blood flow is:

$$Q = \frac{\Delta P}{R}$$

where the letters are as defined above.

The flow of blood through a smooth, straight vessel behaves as if there are concentric laminae, with the fastest flow in the centre creating a paraboloid wave front. The smaller the vessel becomes, the closer the central lamina becomes to the vessel wall. While this formula and lamina flow holds true for a straight, smooth vessel, any deformity, such as vessel angulation, branching, obstruction or intraluminal irregularity, will interfere with lamina flow. Disturbance in lamina flow is known as turbulence. Because all the flow is no longer in the same concentric laminae, fluid flowing across the direction of flow down the vessel will increase resistance to flow. Resistance to lamina blood flow in a vessel is created by marginal adherence of molecules to the vessel wall.

The smaller the vessel diameter, the closer the fastest flowing central lamina becomes to the margin. Therefore, these molecules become closer to the slow moving marginal molecules which increases the resistance to flow. The effect of reducing the vessel diameter can be expressed as mean velocity of flow (v) and is described in the formula:

$$v = \frac{\Delta P r^2}{8\eta L}$$

where v is velocity in cm/s; ΔP is pressure gradient (dynes)/cm²; r is the radius of the vessel in cm; η is the viscosity in poises; and L is the length of vessel in cm.

The rate of blood flow through a vessel (Q) is related to the velocity of flow (v) multiplied by the cross-sectional area:

$$Q = v\pi r^2.$$

From this and the previous formula can be derived Poiseuille's law:

$$Q = \frac{\pi \Delta P r^4}{8\eta L}.$$

Thus it can be seen that if $Q = \Delta P/R$ and $Q = \pi \Delta P r^4 / 8\eta L$ such that the resistance of a blood vessel (R) is:

1. directly proportional to the viscosity of the fluid and the length of the vessel;
2. the resistance is inversely proportional to the fourth power of the radius. Therefore the smaller

the vessel (r), the greater the resistance of the flow. Thus, any interference with the resting tone in the blood vessel, which reduces the vessel radius, will have a detrimental effect on blood flow.

$$R = \frac{8\eta L}{\pi r^4}.$$

Viscosity varies with the speed of blood flow; the faster the flow, the lower the viscosity because Poiseuille's law does not apply fully *in vivo*. The Fahreus–Lindqvist affect appears with reducing vessel diameter below 1.5 mm. The viscosity of blood in vessels narrower than 1.5 mm is so much smaller that viscosity in the capillaries is half that of large vessels. In a 100-micron arteriole, red blood cells are randomly orientated whilst within a 15-micron vessel more regular orientation of red cells occurs. Bloch¹¹ postulated that the vessel flow has a marginal layer with few cells and red cells congregate in the centre of the stream which reduces the viscosity of the layer in contact with the vessel wall. In the 10-micron capillary, the red cells travel in single file paraboloids, rather than the usual biconcave disc shape.

VESSEL WALL TENSION

From Laplace's law, the tangential vessel wall tension (T) is proportional to the vessel diameter (D) and the pressure exerted across the vessel wall (P) such that:

$$T \propto DP.$$

This has critical importance in a small vessel in which vessel diameter reduces, as does the pressure within the vessel. The vessel will collapse at the point when elastic tension in the vessel wall exceeds the transmural pressure (P). This is known as the critical closing pressure. Any increase in the resting tone in the blood vessel (spasm in the clinical setting) which reduces the vessel radius, will thus have a deleterious effect on blood flow.

The control of blood supply to skin flaps occurs predominantly in the microcirculation. These vessels include arterioles which provide two-thirds of resting systemic peripheral vascular resistance, and venules, capillaries and arteriovenous anastomoses which provide the remainder of the peripheral resistance. Skin capillaries are 10–20 microns in diameter; arteriovenous anastomoses have a diameter of 10–30 microns, while the blood flow through them is approximately 325 mL/100 g/min at 20°C.

Regulating the distribution of blood flow occurs at the arteriolar level at which the muscle wall tone is under dual (systemic and local) control, and has been well discussed by Folkow and Neil¹² and Daniel and Kerrigan.¹³ Skin is not considered a 'vital' organ and therefore has little autoregulation mechanism by which blood flow is

maintained to an organ at all costs (unlike the brain or cardiac muscle). The basal vascular tone in the skin is a neural regulation of both sympathetic vasoconstrictor fibres and cholinergic fibres passing to sweat glands with bradykinin-mediated vasodilatation.

Humoral factors acting on the vessel wall include prostaglandin, bradykinin, histamine, norepinephrine, epinephrine, serotonin and PGF₂α.

The external temperature is the most obvious physical mechanism acting locally on the skin blood vessel. Hypothermia will produce vasoconstriction and reduce blood flow, while hyperthermia will have the opposite effect. Increasing blood viscosity will reduce blood flow, but usually only at extreme conditions of low temperature such as seen in the digits. The myogenic response induced by myogenically active 'pacemaker' cells within the muscle wall is less influential in skin blood vessels because the skin vascular bed is weakly autoregulated.

Local metabolic factors acting on the vessel wall act to promote vasodilatation in response to hypoxia and acidosis, hypercarbia or hypercalcaemia.

SYMPATHETIC INNERVATION

The vasomotor response of the autonomic nervous system produces noradrenaline release from sympathetic vasoconstrictor fibres in the walls of arterials, veins and arteriovenous anastomoses. Noradrenaline release produces an alpha adrenergic vasoconstriction. There is no parasympathetic innervation to the skin.

THE COMPROMISED SKIN FLAP

'The after care is as important as the planning' is the fifteenth principle postulated by Sir Harold Gillies.¹⁴ His principle reads, 'How futile it is to lose flap or graft for the lack of a little postoperative care. If in any doubt about the progress slip your hands out of your pockets and get down to that haematoma.' This advice holds as true today as it did when the book was published, the most common cause for flap failure being failure to recognize a compromised circulation. Factors affecting flap survival can be considered as either extrinsic or intrinsic.

Extrinsic factors

External compression of the circulation to the flap is either due to a tight dressing, tension in the skin wound closure which more commonly occurs if the flap is angulated over an underlying rigid bony surface or soft tissue swelling, and this can be due to oedema or a postoperative haematoma. The flap is usually blue and engorged, indicative of venous congestion. The prompt release of tight bandages, dressings and removal of wound

sutures may salvage the situation. In very exceptional circumstances, the flap may be repositioned back on to the donor site if there is concern that the pedicle has been kinked, thus following the old adage 'It is better to have a live flap out of position than a dead flap in position'. [*]

Intrinsic factors

Vasospasm in the flap following raising of the flap is a normal physiological response to reduce blood loss. Under normal circumstances, this vasospasm resolves without intravascular thrombosis because the spasm empties the lumen of blood. In the presence of intact endothelium, the coagulation cascade is not activated. Endothelial cell integrity plays a vital role in the maintenance of blood flow. Where flow to the flap is not established (or is compromised for a prolonged period of time) it has been shown experimentally in rabbits that 'no reflow' occurs after a period of several hours of ischaemia. This has become known as the 'no reflow phenomenon' coined by Ames *et al.* in 1968¹⁵ and studied first in flap reperfusion in 1978.¹⁶ In the no reflow phenomenon, reperfusion of the ischaemic tissue results in the formation of oxygen-derived free radicals. Furthermore, it has been shown that the vasodilator effect of acetyl choline is mediated through endothelial production of nitric oxide.¹⁷ The net effect of acetyl choline following reperfusion in the presence of damaged endothelial cells is vasoconstriction.

Nitric oxide is produced by nitric oxide synthase from the amino acid L-arginine. Elegant experimental research in mice with targeted disruption of the inducible nitric oxide synthase (iNOS) gene (iNOS knockout mice) has shown pharmacological and genetic evidence that iNOS activity promoted survival of ischaemic tissue. The administration of nitro-L-arginine methyl ester (a constitutive NOS, endothelial NOS and neuronal NOS inhibitor) significantly increased flap survival in these mice.

In a pig ischaemia-reperfusion injury flap model, there was a disruption of constitutive nitric oxide synthase expression and activity, which may have led to decreased nitric oxide production.

A great deal of laboratory research has been undertaken to reduce flap failure by pharmacological means. Much attention has been paid to drugs that could act as 'free radical scavengers'. Superoxide dismutase has been shown to improve flap survival in animals,^{18, 19} but not in humans. Angel and coworkers^{20, 21} have been at the forefront of superoxide radical scavenger therapy, publishing work on the beneficial effects of the iron chelator deferoxamine. These benefits, however, occur with significant toxicity which can be ameliorated (in pigs) by the conjugated form, deferoxamine-hesperan (DFO-H). DFO-H has a longer half-life, but with reduced efficacy in augmenting flap survival. This was postulated to decrease its ability to reach the intracellular oxygen free radicals.²²

It has also been shown that allopurinol can augment flap survival.^{23, 24} Allopurinol is a xanthine oxidase inhibitor, although elevated levels of xanthine oxidase and malonyldialdehyde have been noted to be elevated in ischaemic flap tissue in animals.²⁵ A beneficial effect has yet to be shown in humans. Innumerable other animal experiments have been performed on such things as antiadrenergic drugs²⁶ and magnesium-ATP (a supply of high energy phosphometabolites),²⁷ both approaches being designed to increase the levels of ATP in the tissues.

Other researchers have looked at prostacycline (PGI₂) and prostaglandin-E₁ (PGE₁). Both cause peripheral vasodilatation and inhibition of platelet aggregation.^{28, 29, 30, 31}

Endothelin-1 (ET-1) is an endogenous vasoactive (vasoconstrictor) peptide, produced in ischaemic flap tissues. In human microvascular breast reconstruction flaps, a statistically significant increase in (skin biopsy) tissue levels of endothelin-1 after clamping of the flap pedicle has been demonstrated. The authors concluded that endothelin-1 levels were elevated in free flaps following reperfusion.³²

Recent studies have shown that this detrimental effect can be blocked in experimental porcine transverse rectus abdominis myocutaneous (TRAM) flaps by tezosentan, a new endothelin receptor blocker. The authors suggest that 'tezosentan improves oxygenation and metabolism in the jeopardized contralateral flap tissue, probably as a result of a decrease in venous vascular resistance and fluid extravasation'.³³

This beneficial effect on the venous outflow would fit with observations on the sensitivity of the human musculocutaneous perforator vessels to vasoconstrictors and vasodilators *in vitro*. The vasoconstrictor potency of norepinephrine, endothelin-1 and a thromboxane-A₂ mimetic were shown to be significantly higher in the vein than in the artery, hence the maximal venous effect of ET-1 blockade.³⁴ The severity of tissue necrosis correlated well with tissue levels of ET-1 in rat skin flaps, whilst topical nifedipine antagonized the vasoconstrictive effects of ET-1.

Topical nitroglycerin (GTN) has also been shown to exert a greater vasodilator effect on the venous circulation than on arterial vessels. Rohrich and colleagues³⁵ reported improved survival of axial flaps in pigs and rats treated with nitroglycerin ointment. Topical GTN paste is used in clinical practice but with variable success. [*]

Direct smooth muscle relaxants nifedipine and verapamil increased flap survival in rats.^{36, 37, 38} These are calcium-channel blockers which act on the vascular smooth muscles to cause vasodilation but are restricted in clinical practice to topical application on to microvascular anastomoses, as there is no trial evidence to support their systemic use.

Surgically induced neutrophil recruitment in skin flaps has been shown to impair flap survival experimentally in the rat.³⁹ Myeloperoxidase (a marker for neutrophil

recruitment) was significantly reduced by low-dose intraperitoneal calcitonin gene-related peptide (CGRP) without affecting the circulating neutrophil count, with improved random pattern flap survival.

One Japanese group⁴⁰ have studied sulphatide which binds to P- and L-selectin, important in the initiation of neutrophil-endothelial interactions. Pretreated experimental skin flaps showed little histological evidence of leukocyte invasion compared to that in the dermal layer of control flaps 48 hours after flap elevation. They went on to show augmented protection against ischaemia-reperfusion in rat skin flaps when combining sulphatide with anti-rat ICAM-1 and anti-rat LFA-1 antibodies.

The monoclonal antibody to the primary neutrophil adherence-mediating glycoprotein CD18 improves the survival length of the random pattern flap. Histological examination 24 hours after reperfusion in the treated group demonstrated only slight leukocyte invasion into the flap, and myeloperoxidase activity 24 hours after reperfusion was significantly reduced. This study indicated that sulphatide and monoclonal antibodies combined protect rat skin flaps from ischaemia-reperfusion injury.⁴¹

The platelet glycoprotein IIb/IIIa receptor antagonist Abciximab promoted experimental skin flap survival secondary to blocked platelet activation/aggregation and decreased activated-platelet deposition on the vascular endothelium in the rat.⁴² Thus, administration may save the skin flap from reperfusion injury after a long period of ischaemia.

Dimethylsulfoxide (DMSO) is the only substance which has been shown experimentally to improve flap survival in animals and then been supported in a randomized control trial of mastectomy skin flap survival by Rand-Luby *et al.*⁴³ [***] This is one of only two controlled trials referenced by the Cochrane database. The authors concluded that the topical application of DMSO safely reduced human mastectomy skin flap ischaemia.

The other clinical trial on the Cochrane database reported a selective phosphodiesterase III inhibitor (Amrinone) which prevents breakdown of cyclic adenosine monophosphate.⁴⁴ Statistically proven to improve positively the microcirculatory blood flow of transferred flaps, the authors proposed that this occurred by relief of intraoperative vasospasm. [***]

More recent work in rats by Pang *et al.*⁴⁵ concluded that the administration of exogenous vascular endothelial growth factor (VEGF) 'could protect flaps from ischemia-reperfusion injury through the regulation of proinflammatory cytokines and the inhibition of cytotoxic nitric oxide production'.

Adenovirus-mediated gene therapy with vascular endothelial growth factor delivered into the subdermal space of compromised epigastric skin flaps in a rat model has improved skin flap survival.⁴⁶ Viral transfection with subdermal injections of adenovirus-encoding VEGF (Ad-VEGF) was performed two days before flap elevation.

Compared with controls, a significant reduction in the area of necrotic and hypoxic zones of the flap was demonstrated following both local and midline subdermal injections of Ad-VEGF.

Others have reported that the survival of flaps treated with VEGF A165 or B167 cDNA was significantly greater than that of controls.⁴⁷ However, neither study could produce evidence that the mechanism was due to angiogenesis using light microscopy, microvessel count or angiography on the treated flap. This is in contrast with histologically demonstrated angiogenesis at the skin paddle-recipient bed interface following the subcutaneous administration of VEGF into the recipient bed of a skin tube flap.⁴⁸

Further support for VEGF therapy comes from Kryger *et al.*⁴⁹ who showed that all routes of administration (systemic, subdermal into the flap, subfascial into the recipient bed and topical on to the recipient bed) improved survival of a full thickness random pattern flap in the rat compared with controls.

By contrast, Rinsch *et al.*⁵⁰ demonstrated that FGF-2, was more efficacious than either VEGF(121) or VEGF(165) in treating acute skin ischaemia and improving skin flap survival when delivered from encapsulated cells positioned under the distal flap.

Thus, with improved delivery strategies, VEGF and FGF-2 may have a role in the management of surgical ischaemia. However, novel gene therapies to improve flap survival have not yet been translated into clinical flap surgery.

Dextran and heparin have been shown to improve flap survival in experimental studies of microvascular anastomoses, but not in improving survival of a failing flap.^{51, 52} [*]

PHYSICAL INTERVENTIONS

Surgical delay

The only well-established technique to improve skin flap survival is by the 'delay procedure' with which all surgeons should be familiar. 'Delay' is a surgical procedure that renders a flap partially ischaemic several days prior to its transfer in order to increase its viability at transfer. Though much debate exists regarding the actual mechanism of vascular delay, most agree that changes in the microcirculation play a key role.

The latest work by Dhar and Taylor⁵³ showed that when a flap is delayed, there is dilation of existing vessels within the flap, not ingrowth of new vessels. The maximal anatomic effect on the arterial tree occurs at the level of the reduced-caliber 'choke' anastomotic vessels that link adjacent vascular territories.

They describe 'an active process associated with both an increase (hyperplasia) and an enlargement (hypertrophy)

of the cells in all layers of the choke artery wall and a resultant increase in calibre of these vessels.'

Tissue expansion can be considered a form of skin flap delay, where expanded porcine flaps showed 150 percent greater length survival compared with acute nondelayed flaps.⁵⁴ The expanded flaps had 50 percent greater length survival compared with delayed flaps. Angiography showed increased axial vessel calibre in the tissue expanded flaps, subsequently confirmed by Taylor's work. A controlled clinical trial of TRAM flap breast reconstruction confirmed by colour flow Doppler showed an increase in the diameter of flap vessels in which surgical delay was performed one month prior to transfer.⁵⁵ A lower flap necrosis rate was found using a delayed TRAM (7.1 percent) compared with a standard standard TRAM (30 percent). [***]

Lasers

Low energy helium-neon (He-Ne) laser irradiation has been shown to improve the viability of skin flaps in rats⁵⁶ and in clinical flap repair after avulsion injury.⁵⁷ [***] In rat capillaries and fibroblasts, proliferation was demonstrated histologically while clinical improvement was attributed to improved superoxide dismutase activity.

Leeches

Hirudo medicinalis, the medicinal leech, exerts its effect by injecting hirudin, a naturally occurring anticoagulant, into the affected part. In addition, leeches secrete hyaluronidase into the tissues, as well as a vasodilator, which contributes to prolonged bleeding. The main use for leeches is in the congested microvascular flap when there is no other way of improving venous outflow.⁵⁸ [**] Useful in selected cases, there is nonetheless a serious risk of secondary infection with the leech enteric organism *Aeromonas hydrophila* which can kill the skin flap. Antibiotic cover should be provided when using leeches.

KEY POINTS

- Despite a great deal of research into the physiology and pharmacological manipulation of failing or compromised flaps there is no consensus about the clinical application of any of the research methods described.
- Dimethylsulphoxide, amrinone and low energy laser may have a role to play in the prevention of flap ischaemia.

Best clinical practice

- ✓ The only well-proven techniques for augmenting flap survival are preoperative surgical delay or tissue expansion (Recommendation B).
- ✓ 'Prevention is better than cure' is as true today as it was in times past. Meticulous flap planning to preserve a reliable vascular pedicle and avoidance of any extrinsic postoperative compression is vital.
- ✓ Relevant biennial updates beyond the scope of this review can be obtained through *Selected readings in plastic surgery*.⁵⁹

SEARCH STRATEGY

The data in this chapter are supported by a PubMed search using the key terms biomaterials, implants, tissue engineering, otology, rhinology, laryngology and otorhinolaryngology.

INTRODUCTION

Biomaterials have been defined as nonviable materials used in medical devices intended to interact with biological systems,¹ the aim being to replace or repair tissues. Many materials have been used in such roles, with the use of materials such as gold in dental applications being one of earliest described. Polymeric materials were used in dentistry and cardiovascular surgery around the middle of the twentieth century and this was paralleled by the use of metals and polymers in orthopaedics, leading to the Charnley total hip prosthesis in the early 1960s. The term 'biomaterials' was, however, not coined until the late 1960s and the Society for Biomaterials was formed in 1975, reflecting the growing field of biomaterial science.

In the field of otorhinolaryngology (ORL), the use of biomaterials has paralleled the development that has occurred with biomaterials in other fields such as dentistry, cardiovascular and orthopaedic surgery. Early applications were found in reconstructive middle ear surgery using materials such as vinyl-acrylic, polyethylene, polytetrafluoroethylene (PTFE) polyamide and stainless steel wire.^{2,3} Despite initial improvements in middle ear

reconstruction, early attempts were disappointing due to extrusion.^{3,4} It was not until the 1980s that biomaterial ossicular prostheses provided acceptable results with the introduction of hydroxyapatite devices.^{3,5} Hydroxyapatite, along with metals such as titanium, has also found applications in skeletal augmentation and reconstruction, whereas a range of polymers have been used in soft tissue augmentation and reconstruction. [***/**]

The field of biomaterials science is by necessity an interdisciplinary area. For the successful development and deployment of medical devices, a variety of critical areas need to be understood and optimized. These include toxicology, implant design, surgical technique, sterility, implant movement, biodegradation and the biological reaction to implant surfaces. Whilst it is true that there is tension between the surgical requirements and the properties that materials possess for many current applications, the majority of these areas have a good knowledge base. There remains, however, a poor understanding of the biological reaction to implant surfaces at the molecular level. Considerable research is currently being undertaken in this area, in parallel with efforts to tailor novel materials with specific properties, in an effort to engineer a third generation of biomaterials that better

match their proposed function.⁶ Whilst the previous generations of biomaterials were used primarily for tissue replacement, being selected for inertness or subsequently bioactivity, the emphasis is now on tissue repair, stimulating specific cellular responses at the molecular level, as highlighted by the developing field of tissue engineering.

BIOCOMPATIBILITY

Biomaterial and implant biocompatibility are essential requirements for the success of an implanted device. The concept of biocompatibility goes much further than merely assessing the cytotoxicity of a material, but takes into account the reaction of the body to the implant and, of equal importance, the reaction of the implant to the body. Indeed, biocompatibility has been defined as the ability of a material to perform with an appropriate host response in a specific application,¹ implying that materials may be defined in terms of their biocompatibility for specific applications rather than making a general designation.

A key factor in the success or failure of a biomaterial in a specific application is the interaction between the biological milieu and the material surface. Biomaterials have been classified according to the manner of interfacial reaction. A biomaterial may be termed 'bioinert' if the body does not react at all to the implant material. It is biotolerant if, after the initial reaction, the implant is well tolerated, although walled off by a fibrous capsule (almost all bioinert materials show a minimal biotolerant-type response) or bioactive if the implant has a biologically active surface which results in an intimate interfacial bond at the implant site.

These responses are associated with wound repair and foreign body reactions.^{7,8} The type and severity of any response may vary according to the class of biomaterial. With biotolerant materials, the fibrous capsule may be more extensive and associated with the presence of inflammatory cells. A material that is considered bioactive would typically form an intimate chemical bond with the surrounding tissue without an intervening fibrous capsule. The thickness of a fibrous membrane has been used to assess metal reactivity. Titanium typically provokes a very slight fibrous response. Bioinert ceramics generate a minimal tissue reaction, whilst bioactive ceramics tend to form a direct interfacial bond, for example, with bone. Polymeric materials without additives tend to be relatively inert. However, the tissue response to reactive polymers differs from that of reactive metals in that membrane thickness does not correlate well with polymer reactivity, being better assessed by the degree of necrosis and inflammation produced by an implanted polymer in the surrounding tissue.

Biomaterials may be divided into three main groups: metals, polymers and ceramics. These may be further divided into composites, degradable materials, synthetic

and natural polymers. Each of the main groups of materials will be considered in turn as they all have applications relevant to ORL.

Metals

Metals were the earliest class of material to be used as a biomaterial and are largely involved in skeletal and dental applications. The three main classes of metals and alloys currently used to construct surgical implants are:

1. 316L stainless steel;
2. cobalt-chromium (Vitallium being the trade name of the most popular formulation for surgical implants);
3. titanium and titanium alloys.

Metal plates are utilized for skeletal repair, based on their ability to match the supportive and protective functions of bone. However, other properties besides strength, such as corrosion resistance and biocompatibility, require consideration. Titanium is the preferred implant metal for craniomaxillofacial skeletal repair.

The effective use of stainless steel in the maxillofacial region is limited to wires, pins and plates.⁹ Whilst possessing adequate physical properties for most maxillofacial applications, stainless steel loses its biocompatibility over time, has the potential for stress-shielding if it is not removed and has the greatest degree of corrosion of all the metals used for implantation. In contrast, titanium forms a stable titanium oxide layer on its surface upon exposure to oxygen. This is renewed even in biological fluids and allows titanium implants to remain chemically inert and stable to corrosion. Titanium has the additional advantage of osseointegration and when implanted in bone, the bone will grow in intimate proximity to the implant resulting in a permanent solid implant.⁹ [***/**]

Both stainless steel and Vitallium are also known to leach nickel, chromium and molybdenum into surrounding tissues. Titanium plates release titanium dioxide, but no adverse reactions to this have been identified and titanium also possesses advantages in terms of imaging characteristics.¹⁰ [***/**]

In ORL applications, titanium has been used for ossicular prostheses and virtually all long-term clinical studies have been favourable.¹¹ Migration or slippage of the ossicular prosthesis has replaced extrusion as the most common cause of failure that occurs with other prostheses, other than host factors.¹² A recent clinical study reported the extrusion rate to be less than 1 percent and these were associated with resorption of the interposed cartilage layer.¹³ The main area of development has been in the design of the prosthesis, with the strength of titanium allowing for variety in the shapes and sizes of implant that can be machined. Both stainless steel and titanium are utilized in implantable hearing devices as coatings, wires, electrodes and casings. [***/**]

Ceramics

Ceramics can broadly be described as refractory polycrystalline compounds, typically with high compressive strength. Ceramic biomaterials range from being relatively bioinert to bioactive. Attention will also be given to glass ceramics and ceramic-containing composite materials in this section. Bioactive ceramics, glasses and glass ceramics have long been known to interact and bond to living bone. Calcium phosphate-based bioceramics have been used for over 20 years as implants, in periodontal treatment, alveolar ridge augmentation, orthopaedics, maxillofacial surgery and ORL.

Hydroxyapatite (HA) is the most common calcium phosphate bioceramic used in ORL applications. It is similar in chemical composition to the inorganic constituents of living bone. Hydroxyapatite use in ORL was adapted from the field of dentistry and pioneered by Professor Jan Grote and others in the form of prosthetic ossicles for middle ear surgery. Development programmes with animal models indicated good integration without signs of extrusion.¹⁴ These results have been shown to be consistent with studies in humans. For example, Goldenberg and colleagues reported that a HA/Plastipore hybrid implant for tympanoplasty can be placed in direct contact with the tympanic membrane without the requirement for an intervening tissue layer to prevent extrusion.¹⁵ Evaluation of long-term clinical outcome using hydroxyapatite hybrid prostheses indicate stable hearing results with low extrusion (5 percent). Extrusion rates have been shown to rise when prostheses are placed in contact with the tympanic membrane, but this can be reduced (13.2–1.9 percent) by the interposition of autologous cartilage.^{16, 17} Hydroxyapatite has also been used in a porous form as a canal wall prosthesis.¹⁸ [***/**]

Composites containing hydroxyapatite have found ORL applications. Commercial examples of these include HAPEX, a high-density polyethylene (HDPE)/hydroxyapatite composite and Flex HA, a silicone rubber/hydroxyapatite combination. Applications for these include middle ear implants and skeletal augmentation (Figure 10.1).

For example, HAPEX has been used for an ossicular replacement prosthesis,¹⁹ combining HA biocompatibility with mechanical advantages conferred by the composite form.²⁰ Hapex is a homogenous, osteoconductive biomaterial that is comprised of 40 percent hydroxyapatite and 60 percent polyethylene by volume. This results in a material that approximates the mechanical strength of cortical bone, yet is soft enough to cut with a knife. HAPEX also has good sound conduction properties because of its rigidity. [***]

Whilst hydroxyapatite remains the only ceramic that is widely used on a commercial basis for ORL applications, several other biomaterials require attention within this category. Two silicates (glass ceramics)

with middle ear applications are Bioglass and Ceravital®.^{20, 21} Such materials demonstrate bioactive properties in that, on implantation, they develop an apatite-rich gel layer that results in deposition of collagen and bone mineral, producing a chemical bonding between implant and tissue. This interfacial response has been exploited in ossicular replacement and canal wall surgery. [****/***]

Ionomer cements are hybrid glass polymer composites formed by the neutralization reaction of a basic ion leachable inorganic glass and an organic polyelectrolyte (polyacrylic acid). Their properties include high compressive strength, the release of potentially osteoconductive ions such as calcium and fluoride, chemical adhesion to bone and metal and the ability to mould and shape to an implant site. Ionomer cements are established restorative dental materials and have been used as preformed implants and cements in ORL and cranial surgery.^{22, 23} Possible complications include central nervous system (CNS) disturbances due to leakage of aluminum ions when the cement is in contact with cerebrospinal fluid (CSF), damage to structures (e.g. facial nerves, inner ear) by direct contact, foreign-body reaction and deficient wound healing of structures over implanted cement.²⁴ The successful clinical use of glass ionomer cement (GIC), both as bone cements and as preformed implants for hard tissue replacement, have been reported in cochlear implant fixation, the repair of the tympanic chain and eustachian tube obliteration. They have also been used for prosthetic implants such as ear ossicles, and as a bone substitute for oral and reconstructive surgery, for example Serenocem^{TM25} (Figure 10.2).

The major application in otological surgery, where GICs have no near rival for clinical efficacy, is in the reconstruction of the ossicular chain, and where the cement can be used to repair the bony ossicles in their normal position and cement cochlear implants.²⁵ [****/***]

Polymers

There are many forms of polymer, both natural and synthetic, and a wide variety have been tested as some form of surgical implant. For a biomaterial implant, a polymer needs to be selected or developed, which has properties that are close to those required for a particular application.

Polymers possess certain advantages for use as biomaterials, including:

- variety of mechanical and physical properties;
- malleability;
- moderate inertness to host tissue;
- reasonable cost.

Their disadvantages include:

- general nonbiocompatibility (due to the leaching of toxic substances);
- a lack of resistance to the harsh tissue environment.²⁶

Polymers have been extensively used in ORL for middle ear surgery, where they have been used as ossicular replacement prostheses, but their performance has varied. Synthetic polymers that have seen application in this regard include PTFE and polyethylene (PE).

Proplast is a PTFE-based material whose initial embodiment as an ossicular replacement was as a spongy graphite composite, but which evolved to include both alumina and hydroxyapatite. It was removed from the US market after released particulate debris led to many chronic inflammatory responses following implantation

in vivo.²⁶ A PTFE-based material used as a stapes prosthesis that is not reactive with the tissue, is Teflon. However, this feature can lead to slippage of the device if not placed properly.²⁷ [***/**]

Plastipore and Medpore are trade names for HDPE implants. They are noncompressive, chemically inert sponges that permit soft-tissue and bone ingrowth.²⁶ Two basic prosthesis types have been used in middle ear reconstructive surgery: total ossicular replacement prosthesis (TORP) and partial ossicular replacement prosthesis (PORP).

For all these synthetic polymer prostheses used in ossicular reconstruction, the major failing has been high extrusion rates in long-term clinical studies.¹¹ The insertion of a thin sheet of tissue (autograft cartilage) between the head of the prosthesis and the tympanic membrane can help reduce the extrusion of Plastipore implants.²⁸ Satisfactory long-term results with Plastipore using this procedure in large series have been reported by several sources (typical extrusion rates of 4 percent).^{29, 30} [***/**]

PTFE has also been used in nasal dorsum surgery, both in injectable form and as a solid nasal dorsal implant.³¹ A further application for PTFE been used in the form of Gore-Tex®, which has a long record of tissue compatibility by virtue of its use in vascular surgery. Gore-Tex sheets manufactured for facial surgery can be custom cut and layered to create a natural-appearing nasal dorsum.³² Gore-Tex has also been used for facial reconstruction in areas including the frontal bone, orbital rim, malar complex and nasal tip. The mild foreign body reaction, minimal fibrous tissue ingrowth and its mouldable nature enables Gore-Tex to conform to surrounding profiles and lends itself to excellent visual tissue-filling capabilities with minimal palpability in subcutaneous augmented site.³³ However, Gore-Tex has been reported to have an infection rate of 2–3 percent.³⁴ [***/**]

Nasal reconstruction has also seen the application of polyethylene terephthalate (Mersilene) and HDPE (Medpore). Both implants allow tissue ingrowth, which reduces problems of implant mobility, but the stiffness of Medpore means it does not feel as natural over the nasal bridge.³² Reported long-term clinical experience with Medpore used for nasal reconstruction and the correction of craniofacial deformity claim that 87 percent of patients remain free of complications.³⁵ [***/**]

Silicone is also of interest in ORL. A pure form of silicone rubber is marketed as Silastic. Clinical experience with Silastic as a solid silicone rubber implant in nonload-bearing areas (nasal dorsum, chin) is extensive. Complications of infection, migration, extrusion and changes in the overlying skin have been reported, occurring at widely varying incidence.^{32, 36, 37} [***/**]

Silicone elastomer implantation has been used for medialization of a paralysed vocal cord. This proved more effective than Teflon injection, the shortcomings of which include its irreversibility and granuloma formation and

acute reactions including erythema, fever, transient hoarseness and cervical lymphadenopathy.^{38,39} [***/**]

A further application for silicone elastomer is with the intracochlear electrode used in cochlear implants. The electronic unit is also covered by hard Silastic and sealed within a ceramic or titanium case, with further insulation of the electrode array by Teflon being necessary. Despite this range of biomaterials, there have been no documented cases of rejection of this type of cochlear implant.⁴⁰

The advantages of silicone elastomer implants include shaping to precise dimensions at the time of surgery, the reversibility of the procedure and a more predictable result. However, concern is increasing regarding the safety and local and systemic effects of silicone implants.³⁸ [***/**]

TISSUE ENGINEERING

A large part of modern medical practice is aimed at the restoration of function by replacement of damaged or diseased tissues and organs. Replacement and repair is either by using artificial implants or by transplantation of tissues.⁴¹ Such interventions are hindered by factors such as immune rejection, limited supply and donor site morbidity.

The fundamental premise of tissue engineering is the regeneration of tissues and restoration of function of organs through implantation of cells/tissues grown outside the body or stimulating cells to grow into an implanted matrix.⁴² Tissue engineering has evolved from the use of biomaterials to repair or replace diseased or damaged tissue to using controlled 3D scaffolds in which cells can be seeded usually prior to implantation, as shown diagrammatically in **Figure 10.3**. This living tissue construct is functionally, structurally and mechanically equal (if not better) to the tissue it has been designed to replace.⁴²

A major advantage with this approach is that tissues can be designed to grow in such a way that they precisely match the requirements of the individual in terms of size, shape and immunologic compatibility, minimizing the need for further treatment. The clinical success of the

construct is largely dependent on the quality of the starting materials, i.e. scaffold composition, and of key importance is a suitable supply of cells. There are a number of different sources of cells that could be used for tissue repair and regeneration. These include mature (non-stem) cells from the patient, 'adult' stem cells from the patient such as bone marrow stromal (or mesenchymal) stem cells and embryonic stem (ES) cells/embryonic germ (EG) cells.⁴³ Scaffolds may be composed of polymers, metals, ceramics or composites. It is important to select a material that closely matches the properties of the tissue that it is to replace. Scaffolds intended to replace soft tissues such as skin, tendon, ligament, breast, eye, blood vessels and heart valves tend to be composed of natural and synthetic polymers. Replacement of hard tissues, such as bone and dentine, tend to use metals, ceramics, composites and polymers.

Characteristics of scaffolds

The primary function of a scaffold is to allow cell attachment, migration on to or within the scaffold, cell proliferation and cell differentiation. It must also provide an environment in which the cells can maintain their phenotype and synthesize required proteins and molecules. The characteristics required of scaffolds include high porosity, high surface area, structural strength, specific 3D shape and biodegradability if necessary. A porous structure provides an implant with two critical functions. Firstly, pore channels provide ports of entry for migrating cells or for capillary suction of blood. Secondly, a large area is available for specific and numerous cell interactions. An example of a porous scaffold, currently under investigation for bone repair,^{44,45} is shown in **Figure 10.4**.

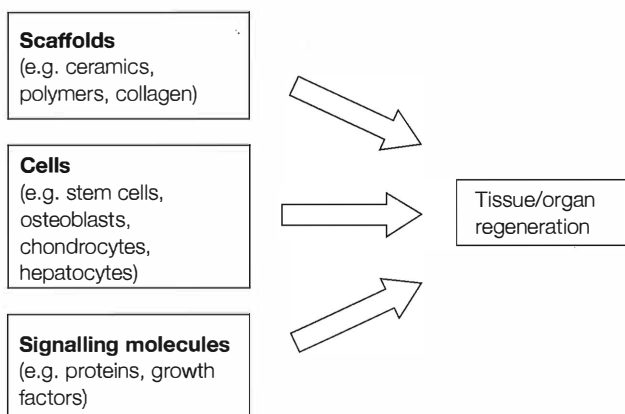

Figure 10.3 Key factors involved in tissue engineering.

Figure 10.4 Scanning electron micrograph of a porous 58S bioactive glass produced using a foaming technique. Courtesy of Julian R Jones, Imperial College of Science, Technology and Medicine, London, UK.

Biodegradable materials are required for repair or remodelling and not necessarily long-term stability. Manufacturing feasibility, the ability to form final product design, and short-term mechanical properties with negligible toxicity from degradation products are prerequisites essential for these materials.

Types of scaffold materials

Materials can be subdivided into those derived from naturally occurring materials and those manufactured synthetically.

NATURAL MATERIALS

Examples of natural materials include collagen, glycosaminoglycans (GAG), chitosan and alginates. The advantages of natural materials are that they have low toxicity and a low chronic inflammatory response. They can be combined into a composite with other natural materials or synthetic materials (thereby having the mechanical strength of the synthetic material, as well as the biocompatibility of the natural material) and can be degraded by naturally occurring enzymes. The disadvantages, however, include poor mechanical strength, as well as a complex structure and hence manipulation becomes more difficult. They can be easily denatured and often require chemical modification, which can lead to toxicity.^{46, 47, 48, 49} An example of a commonly used natural material is collagen. This is a major protein of the extracellular matrix, which is a component of connective tissues and can provide mechanical support. Collagen is a fibrous protein with a long, stiff, triple-stranded helical structure. The three predominant types are type I found in skin and bone, type II that is predominant in cartilage and type III which is predominant in the wall of blood vessels.⁵⁰

As mentioned previously, natural materials often require chemical modification. Collagen can be modified to increase strength by a variety of methods including crosslinking by dehydrative methods or chemical methods, e.g. glutaraldehyde.^{48, 51, 52} Collagen can also be made into a porous scaffold by freezing in a dilute suspension and then inducing sublimation of the ice crystals by exposure to a low temperature vacuum,⁵³ as shown in Figure 10.5. By adjusting the kinetics of ice crystal formation to the appropriate magnitude and direction, pores from the ice dendrites are eventually sublimed.⁵³

Clinical applications of collagen scaffolds are highly relevant to otorhinolaryngological practice. These include the manufacture of sutures, haemostatic agents (powder, sponge, fleece), blood vessels (extruded collagen tubes), tendons and ligaments, dermal regeneration for burn treatment and peripheral nerve regeneration (e.g. porous collagen-GAG copolymer).⁵⁴

SYNTHETIC SCAFFOLD MATERIALS

Polymers

Absorbable polymers include polyglycolide (PGA), polylactide (PLA) and polylactide-coglycolide (PLG) which are used for sutures and meshes, as well as polydioxanone which is also used for intramedullary pins. Nonabsorbable PTFE used in vascular grafts and periodontal inserts, nylon and polyethylene terephthalate (PET) used for sutures, meshes and vascular grafts (for a review of polymer applications see *Principles of tissue engineering*⁵⁵).

Ceramics and glasses

Ceramics and glasses encompass a wide range of inorganic/nonmetallic compositions and are particularly used to repair or replace bone. Table 10.1 shows examples of ceramics and bone tissue attachment to them.

Bioactive glasses

These are based on a silica (O–Si–O) network structure with ions such as calcium, sodium and phosphorus. Bioactive glasses have been investigated for applications in bone repair and engineering due to their ability to form a bond to living bone which has been attributed to the formation of a biologically active hydroxycarbonate apatite (HCA) layer.⁵⁶ This HCA layer is chemically equivalent to the inorganic part of bone.⁵⁷ Interestingly, they have been found to stimulate genes in osteoblasts⁵⁸ causing upregulation of various osteoblast-specific genes.

There are two categories of bioactive glass: melt derived and sol-gel derived. Melt-derived glasses are produced by the melting and mixing of oxide components in a furnace. They are mainly quaternary such as Bioglass® (46.1 percent SiO₂, 24.4 percent Na₂O, 26.9 percent CaO and 2.6 percent P₂O₅). Bioglass can be cast into any shape or powder size and is commercially available as Novabone® (US Biomaterials, Jacksonville Beach, FL, USA).

Sol-gel-derived glass is manufactured by the mixing of alkoxide components in solution in a fume hood (sol).

Table 10.1 Bone tissue attachment to bioceramics.

Bioceramic	Bone tissue attachment
Single crystal Al ₂ O ₃	Dense nonporous nearly inert ceramics.
Polycrystalline Al ₂ O ₃	Bone growth into surface irregularities by cementing the device into the tissues or by press fitting into a defect (morphological fixation).
Polycrystalline Al ₂ O ₃	Porous inert implants – bone ingrowth occurs that mechanically attaches the bone to the material
Hydroxyapatite (HA) coated porous metals	(biological fixation)
Bioactive glasses	Dense porous/nonporous surface reactive ceramics, glasses and glass-ceramics attach directly by
Bioactive glass ceramics	chemical bonding with bone (bioactive fixation)
HA	
Calcium sulphate	Dense porous/nonporous resorbable ceramics slowly replaced by bone
Tricalcium phosphate (TCP)	
Calcium phosphate salts

Polymer reactions then form a silica network (gel). They are mainly ternary, binary or pure silica materials, which have a mesoporous texture with enhanced bioactivity and resorbability.

Types of scaffolds

Scaffolds can be manufactured in many forms to give their required characteristics for specific applications. Fibre scaffolds have a large surface area to volume ratio with high porosity. They can be used in conjunction with other scaffolds to form a composite with added strength. They can be tubular, e.g. for nerve, blood vessel and intestine, or solid. Fibres and fibre scaffolds are commonly composed of PLA, PGA, PLG or glass. Textile fabrics are produced from woven, nonwoven and knitted fibres and are composed of a wide range of natural and synthetic, absorbable and nonabsorbable fibres. They can be used for wound repair in the form of sutures and reinforcing meshes, tendons and ligaments.

Clinical applications

Each tissue type has specific requirements, which are due to the cell types within the tissue, the function of the tissue, mechanical requirements such as load and flexibility and finally, the specific environment in which the tissue is located.

BONE

Bone is an example where mechanical strength is a predominant feature required of the scaffold. It needs to be strong enough for load-bearing sites, yet not too strong as stress shielding problems may occur.⁵⁹ For osteoblasts

to undergo an ideal process of new bone formation, the scaffold must have interconnective porosity. The ability of the scaffold to be produced as a 3D anatomical shape is also an essential feature.

Successful bone repair in a sheep model has been accomplished using a coral scaffold seeded with *in vitro* expanded marrow stromal cells/mesenchymal stem cells⁶⁰ as shown in **Figure 10.6**. Formation of new medullary bone with mature lamella cortical bone was achieved. Coral is a natural exoskeleton where inorganic calcium carbonate grows on to a charged organized organic template and has been used in various clinical applications.^{61, 62, 63, 64, 65} This natural ceramic has the best mechanical properties of the porous calcium-based ceramics due to its interconnected porous architecture, similar to that of spongy bone.^{66, 67}

CRANIOFACIAL BONE (RECONSTRUCTIVE AND COSMETIC)

This is a nonload-bearing site and patient-specific shapes are crucial. An example of such an area is repair of the orbital floor. Success of this procedure is crucial for binocular vision. Titanium is used most frequently but has many disadvantages, such as migration of the implant and hence occasionally necessitating further surgery for extrusion. Although there has been a move towards degradable materials in recent years, these also have the disadvantage of losing their mechanical strength, leading to sagging of the implant and potential loss of binocular vision. Recently, research has focussed on the development of new composite materials for improved cranio-facial bone repair, comprising polycaprolactone reinforced with phosphate glass-long fibres.^{68, 69, 70} Ideally, machining of a patient-specific implant controlled by computerized tomography (CT) scan data from the patient would be standard manufacturing protocol in the future (**Figure 10.7**).

Figure 10.6 New bone formation using a cell-seeded coral scaffold. Microradiographs and photomicrographs after 16 weeks. Histological sections of defects (a) left empty or filled with (c) coral (e) coral-FBM (fresh bone marrow) and (g) coral-MS. Fibrous tissue (FT) has invaded the defect in (a) and (e). In defects filled with coral alone (c), osteogenesis occurred within the medullary canal (MB). Defects filled with coral and MSC show cortical-like bone formation peripherally (CB). Cortical continuity was achieved between the edges of the defect. Microradiographs confirmed the histological observations. There was no bone formation in the defects left empty (b) or filled with coral-FBM (f). Bone formation occurred in the medullary area in defects filled with coral alone (d), but was insufficient for bone union. In contrast defects filled with coral-MS (h) show osteogenesis chiefly at the periphery of the defect, leading to cortical bone union of the defect. CARTILAGE

Cartilage is a nonvascular tissue and therefore has a limited capacity for self-repair. *In vivo* chondrocytes have a rounded morphology but often *in vitro*, become fibroblastic and lose their rounded phenotype and this may alter gene expression. Therefore, an ideal scaffold would retain the rounded morphology of chondrocytes. One such material that does possess this property is poly (ethylmethacrylate)/tetrahydrofurfuryl methacrylate (PEMA/THFMA),⁷¹ which has been proposed as a material for cartilage repair.⁷² Other materials that have been investigated for cartilage repair include hydrogels,⁷³ collagen matrices⁷⁴ and PGA/PLA.^{75, 76}

The most widely held public perception of tissue engineering is research performed by Cao *et al.*⁷⁵ A scaffold was composed of PGA/PLA as a nonwoven mesh and produced in the shape of a human auricle. The mesh was then seeded with bovine articular cartilage chondrocytes and implanted into subcutaneous pockets on the back of athymic mice.

NERVE

Current surgical techniques employed to repair transected peripheral nerves, e.g. facial nerve, are based on suturing nonuniting ends. Improved nerve regeneration is facilitated by the use of conduits. Guided nerve regeneration would also be of benefit. This could be achieved by micropatterning polymer surfaces with extracellular matrix proteins or peptides or by a grooved topography, promoting cell adhesion and axonal outgrowth. Neuronal regeneration with conduit devices, including cellular components, e.g. Schwann cells, are currently being investigated.⁷⁷ For a review of this subject see Fine *et al.*⁷⁸

VASCULAR

The replacement of small-diameter blood vessels by tissue-engineered vascular grafts is a further application that may be of benefit to the otolaryngologist-head and neck surgeon. For example, smooth muscle cells have been seeded into porous PGA tubes and then cultured under pulsing conditions of 165 times/minute.⁷⁹ The interior of the vessel is then coated with endothelial cells (**Figure 10.8**). Tissue-engineered arteries have lasted for more than three weeks without occluding in autologous pig models.

SKIN

A common application of tissue engineering is for the treatment of burn injuries. These cause loss of the skin's integrity, massive fluid loss and microbial invasion. Tissue engineering of skin would be applicable to ensuring adequate coverage in reconstructive surgery. Skin cells can regenerate and repair themselves in many instances, but deep second-degree (partial thickness) or third-degree (full thickness) burns have a decreased capacity for regeneration of tissue and can lose this capacity altogether.

Figure 10.8 An example of a tissue-engineered blood vessel, which maintained successful function when implanted into a pig model. Reprinted with permission from Niklason *et al.*⁷⁹, © 1999, American Association for the Advancement of Science.

There are two well-known examples of skin regeneration scaffolds which are available commercially. They are Dermagraft[®] produced by Advanced BioHealing, Inc. (La Jolla, CA, USA)⁸⁰ and Apligraf[®] produced by Organogenesis (Canton, MA, USA).⁸¹

Dermagraft is produced by seeding stromal cells on to vicryl, a blend of PLA and PGA (produced by Johnson & Johnson, New Brunswick, NJ, USA). This scaffold is then kept under optimal conditions in a bioreactor where the cells multiply and produce collagen, ECM proteins and growth factors. Once it has served its purpose, the scaffold breaks down into glycolic and lactic acid, which is then transported away by the bloodstream and metabolized into CO₂, O₂ and H₂O. A 1-inch square sample yields cells sufficient for 250,000 square feet of final product, each 3 × 4 inch lot produces 1000 units of Dermagraft and is ready for use after 20 days of preparation.

This manufacturing process enables the skin cells to establish their natural organization and enables up to 200,000 units of Apligraf to be produced from a single piece of donated tissue (circumcized infant foreskin). Hence it is available to physicians upon demand, it is easy to use and does not require cryogenic storage.

CONCLUSION

Despite the relative successes in the use of biomaterials in ORL, there remain significant challenges where the desired parameters cannot be met using current materials. Other areas of the field can be said to be still in their infancy. For example, considering ossicular prostheses, whilst biocompatibility parameters are being established, little attention has been addressed to optimizing the acoustic properties of the material used. Similarly, in the field of tissue engineering, optimal materials and parameters are still to be established. Significant improvements in implant performance are associated with a corresponding development in materials, but for each new application of a biomaterial, testing to ensure safety and efficacy must be undertaken.⁴ The most difficult and expensive development for a new medical implant involves materials that have no history as biomaterials, because of the costly and lengthy process of animal and human studies. The developments of new implants for use in ORL will be helped by people working in the area of biomaterials collaborating closely with clinicians. Areas which have posed a particular problem for biomaterials include repair of stenotic trachea, replacement of the larynx, total tympanic membrane replacement, accelerated mucosal healing after sinus surgery and reducing fibrous tissue formation after middle ear surgery. Biodegradable implants that promote tissue regeneration obviate the concern about long-term implant failure due to mechanical mismatch at the implant–tissue interface and show great promise for some of the above applications.

In tissue engineering, the search for a scaffold that will act as a template for tissue growth in three dimensions by having an interconnected macroporous network for tissue ingrowth, vascularization and nutrient delivery continues. The ideal scaffold would also bond to host tissue without formation of scar tissue, and influence the genes of the cells of the local tissue to enable efficient cell differentiation, proliferation and maintenance of the phenotype. Ideally, the scaffold would resorb at the same rate as tissue regeneration and be strong enough to withstand loading where necessary. An ideal scaffold would also be easily and cheaply manufactured and produced to ISO9001/FDA standards.

KEY POINTS

- Biocompatibility is defined as the ability of a material to perform with an appropriate host response in a specific application and is an essential requirement for the success of any implanted device.
- There are three main groups of materials that are used in ORL applications, i.e. metals, polymers and ceramics.
- Titanium is a widely used biomaterial in ORL applications. It has been used for ossicular prostheses with favourable clinical results, as the strength of titanium allows the implant to be manufactured into a variety of shapes and sizes.
- Hydroxyapatite, a calcium phosphate ceramic similar in chemical composition to the inorganic constituents of bone, is the most common bioceramic used in ORL applications, typically as a composite device with metals or polymers.
- Hydroxyapatite polymer composites have been used as implants for tympanoplasty in direct contact with the tympanic membrane, middle ear implants and skeletal augmentation.
- Polymer biomaterials have been extensively used in ORL applications for middle ear and facial reconstructive surgery, for example, total ossicular replacement prosthesis and nasal reconstruction.

Deficiencies in current knowledge and areas for future research

Biomaterials

The development of new materials is essential for progress in the field of implant technology. The majority

of current commercial materials can be improved, whilst for certain conditions, for example laryngectomy, no candidate implant has been successful in restoring natural function. There is a general requirement for a greater understanding of the interfacial responses at the molecular level to improve the fabrication of the next generation of materials. Such materials are likely to include genetically engineered and immunologically prepared natural and synthetic substances, conjugates (probably bioresorbable)²⁶ or biomimetic materials.

It is anticipated that tissue repair will ultimately take over from tissue replacement, hence biomaterials will be utilized more as scaffolds or templates for tissue regeneration rather than using replacement materials. Such a shift will alter the properties sought from biomaterials.

Synthetic biodegradable polymers in the form of scaffolds are being increasingly used to engineer tissues to restore form and function. For example, a scaffold seeded with transplanted chondrocytes has potential for the regeneration of any cartilaginous structure possessing normal cartilage tissue. The scaffold must allow nutrient to pass to cells as well as maintain its 3D shape and have appropriate flexibility and strength. Polyglycolic acid (PGA) and polylactic acid (PLA) remain among the most widely used synthetic materials for such applications. PGA scaffolds, in preformed shapes, loaded with bovine chondrocytes have been implanted subcutaneously in athymic mice with the resulting tissue showing histological evidence of organized hyaline cartilage.^{75, 82, 83} [**]

Natural polymers, such as alginates, have also been used to deliver chondrocytes for cartilage repair.⁸⁴ Natural materials may closely mimic the native cellular environment as they often comprise extracellular matrix components, whereas synthetic materials have the advantage of being able better to control material properties such as strength, degradation time, porosity and microstructure. Cellular attachment to these can be improved by modifying the polymer chemically or by coating it and growth factors to stimulate tissue formation can also be incorporated into such scaffolds.⁸⁵ [**]

Tissue engineering

Research is now focussing on 'third-generation biomaterials'⁶ as materials for tissue-engineering scaffold production. When research into biomaterials began, materials were commonly inert. Research then began to focus on a second generation of bioactive materials that elicit action and reaction in the biological environment.⁸⁶ Now, however, there is a move to third-generation materials which stimulate specific cellular responses at the molecular level.⁶ They are also bioresorbable and can be tailored to suit specific tissues.

INNATE AND ADAPTIVE IMMUNITY

The immune system has evolved for protection against infective agents that invade the body. In order to achieve this, the immune system has recognition properties to locate and identify the invader, and to activate defence processes that repel or destroy the invader. There are an enormous number and variety of infectious agents within the main categories of viruses, bacteria, fungi, protozoa and parasitic worms. In order to provide effective immunity against each of these agents, the immune system has to be able to meet the challenges that they pose: this is achieved by a diverse range of molecular and cellular components of the body that cooperate with each other in order to maximize their defensive activities. Some of these components generate innate immunity, whereas others provide adaptive (or acquired) immunity. The main cell types of the immune system are the leukocytes that develop from stem cells in the bone marrow.

The innate immune system is evolutionarily older than the adaptive system and provides generic defence against categories of microbes. It is composed of a range of cells and proteins found in the circulation and in tissues: these include macrophages (and their monocyte precursors), granulocytes (i.e. neutrophils, eosinophils, basophils) and mast cells, natural killer cells, complement proteins and regulatory proteins called cytokines. The innate system employs an inherited repertoire of receptor proteins (known as pattern-recognition molecules) that recognize characteristic structures that are commonly expressed by microbes, and changes to cells brought about by infection. The advantage of this system is that it is rapidly activated

by infective agents that penetrate tissues. However, it is only moderately efficient, which means that adaptive immunity is also required for the complete elimination of many pathogens.

Adaptive immunity is mediated by T lymphocytes and B lymphocytes (also known as T cells and B cells). Like the leukocytes of the innate system, lymphocytes develop from bone marrow stem cells, but the precursors of T cells migrate from the bone marrow to complete their maturation in the thymus. Each T or B cell expresses receptors that specifically recognize one particular chemical structure of a microbial molecule (known, in this context, as an antigen). Activated B cells also secrete a soluble form of their antigen receptors, known as antibodies or immunoglobulins (Ig). An enormously diverse repertoire of antigen receptors is somatically generated by recombination events involving the receptor genes during the development of lymphocytes, so that potentially millions of different antigens can be recognized. The recruitment, activation and proliferation of resting lymphocytes specific for the antigens of an invading microbe take some time (possibly several days), but the lymphocytes generate highly efficient defence. In addition, some of the lymphocytes activated by specific antigens are maintained in the body as resting cells after the elimination of the infection and constitute a memory population of cells that are able to generate a bigger and faster response upon subsequent exposure to the same antigens: this demonstrates the adaptive properties of lymphocytes.

The innate and adaptive systems are not independent, but interact with each other and synergize to generate

optimal immunity. First, lymphocyte activation is dependent not only on antigen recognition, but also on co-stimulatory signals provided by cells and molecules of the innate system. Second, the antibodies produced by B cells and the cytokines secreted primarily by T cells enhance the defensive activities of the innate system.

Stages of an immune response

The immediate response to an invading pathogen is mounted by innate components resident within the infected tissues (**Figure 11.1a**). In particular, tissue macrophages express a range of receptors for microbial structures, including mannose receptor, scavenger receptors and Toll-like receptors, whose ligands include various microbial polysaccharides and lipids. Complement proteins are also directly activated by microbes via what is termed the alternative pathway (see under The complement system). Inflammatory products of macrophages and complement, together with those released by tissue mast cells activated by the complement peptides C3a and C5a (known as anaphylatoxins), induce the migration of granulocytes, natural killer cells and more complement proteins from the bloodstream into the infected tissues (**Figure 11.1b**).

Whilst these innate processes are providing early defence to limit growth and spread of the infection within the body, other processes are set in train to generate the antigen-specific adaptive response (**Figure 11.1c**). The activation of lymphocytes does not initially take place within the infected tissues themselves, but in specialized lymphoid tissues such as lymph nodes, the spleen and mucosa-associated lymphoid tissues (MALT) that include Waldeyer's ring. Antigens therefore have to be transported from the infected tissues to local lymphoid tissues. Some antigens may be passively carried in the tissue fluid forming the lymph that drains into regional lymph nodes. However, a major part is played by cells found in most tissues called dendritic cells. These, like the macrophages described above, express pattern-recognition receptors for microbial structures, and actively engulf microbial material. This induces the maturation of the dendritic cells, which migrate from the site of infection and carry the microbial antigens to the local lymphoid tissues where T and B lymphocytes have the opportunity to interact with the antigens and be activated by them. Only a very small proportion of the millions of lymphocytes in a particular lymphoid organ will have receptors that specifically recognize the antigens of a particular microbe. It is these specific lymphocytes that are activated by the antigens and proliferate and mature into effector cells that contribute to defence against the pathogen. These effector lymphocytes leave the lymphoid tissues and recirculate via the bloodstream to the site of infection in order to enhance the destruction and elimination of the pathogen in cooperation with the innate components described above.

Figure 11.1 Stages of an immune response: see text for details. (a) Immediate local innate response; (b) early induced response (innate/inflammatory); (c) later adaptive response. Ab, antibody; B, B lymphocyte; C, complement; DC, dendritic cell; LN, lymph node; MΦ, macrophage; N, neutrophil; NK, natural killer cell; T, T lymphocyte.

ANTIGEN RECOGNITION

Antigen recognition involves a high affinity interaction between an antigen and the specialized antigen combining site of a lymphocyte's antigen receptor protein (or of an antibody molecule). The binding involves noncovalent intermolecular attractive forces that require a very close approach between the surfaces of the antigen and the combining site. In other words, the interacting surfaces

must have complementary shapes that fit snugly together (rather like a lock and a key) so that significant attractive interactions occur between complementary chemical groups of the antigen and the combining site. Each lymphocyte clone (i.e. group of cells derived from a single parent lymphocyte) expresses antigen receptors with a single type of combining site that is essentially unique in shape and amino acid composition to that clone compared with the millions of other lymphocyte clones in the body: this is why millions of different antigens can be recognized by the adaptive immune system. Furthermore, the specificity of the adaptive response arises because those lymphocytes whose receptors have the highest affinity for an antigen that enters the body are the ones most likely to bind it and, therefore, to be activated by it: this is termed clonal selection.

B cells and antibodies (immunoglobulins)

The B cell's receptor is essentially a membrane bound form of the antibodies that the B cell secretes, and is called surface immunoglobulin (sIg) (**Figure 11.2**). It is made up of two identical large polypeptides (heavy chains) and two identical smaller light chains (which can be one of two types called kappa and lambda light chains). Each chain is composed of a series of homologous globular regions called Ig domains: two in the light chains and four or five in the heavy chains.

Figure 11.2 A schematic structure of a generic immunoglobulin (surface or secreted), see text for details. The variable domains of the heavy and light chains are labelled V_H and V_L, respectively. Similarly, the constant domains are labelled C_H1–3 and C_L. The region below C_H3 represents the transmembrane region and cytoplasmic tail present in sIg, but not in secreted antibodies.

The receptor has two identical antigen combining sites, each of which is composed of the amino terminal domains of a heavy and a light chain: these are called variable domains because they vary in structure between different B cell clones, thereby conferring the differences in antigenic specificity between B cells. Different types of chemicals can serve as antigens for direct interaction with different B cell receptors and antibodies, including proteins, carbohydrates, lipids and even nucleic acids. The combining site constitutes only a small part of a whole Ig molecule and, for example, can accommodate approximately four to six amino acids of a protein antigen: the precise region of an antigen molecule that interacts with a combining site is termed the antigenic determinant or epitope. Each variable domain contains three hypervariable loops, so called because they differ most in amino acid sequence between different clones of B cells; they are also known as complementarity determining regions because they are complementary to the epitope and form the main interactions with it. Following B cell activation, modifications can occur to the variable domains by somatic mutation. This involves nucleotide changes to the variable domain genes during B cell replication that affect the amino acid sequence (particularly of the complementarity determining regions), and therefore affect the antigenic specificity of the antigen combining sites. This can generate combining sites that fit even better with the epitope and therefore have improved affinity for the antigen.

The other domains are called constant domains because they have the same structure in the sIg of different B cells. Human B cells can express one of nine different forms or isotypes of Ig (both surface and secreted) that differ in the structure and number of their heavy chain constant region domains, and constitute five immunoglobulin classes. These are called IgM, IgG (with subclasses IgG1, IgG2, IgG3 and IgG4), IgA (with subclasses IgA1 and IgA2), IgE and IgD. All B cells are initially programmed to express IgM (plus IgD), but can undergo Ig class switching to produce one of the other isotypes following stimulation by antigen, without changing their antigenic specificity. They do this by changing the heavy chain constant region domains that they express, but maintain expression of the same heavy chain variable domain and the same light chain variable and constant domains.

The sIg is anchored in the surface membrane of a B cell by a transmembrane amino acid sequence at the carboxy terminus of the heavy chains. When a resting B cell is activated by antigen, it can differentiate into a plasma cell that produces large numbers of Ig molecules that lack the transmembrane sequence, and so are secreted from the cell as antibodies with the same antigenic specificity and isotype as the B cell's sIg. Because B cells initially express sIgM, the first antibodies produced during an immune response (i.e. on first exposure to a particular antigen) are also IgM (there is little, if any, secretion of IgD), but IgG, IgA and IgE antibodies appear later in the response as

activated B cells undergo class switching. Furthermore, the memory population is derived from B cells that have undergone class switching, so that IgG, IgA and IgE are produced at the start of a secondary response on repeated exposure to the same antigen. The advantages of producing a range of antibody isotypes are because they have different physiological and defensive activities.

T cells and antigen presentation

The T cell receptor (TCR) for antigen shows both similarities and differences to B cell sIg (**Figure 11.3**). The TCR is a much smaller molecule, being made up of two polypeptide chains each of which is approximately the same size as an Ig light chain, with both expressing a transmembrane sequence: indeed, T cells do not produce a secreted form of the TCR, i.e. they do not release anything equivalent to antibodies. The TCR polypeptides expressed by the majority of T cells are called alpha and beta chains, whereas a minority express gamma and delta chains. Each chain is composed of two domains that show strong structural homologies with those of the immunoglobulins. Similar Ig-like domains are found in many other surface molecules of lymphocytes and other cells: this indicates evolutionary genetic relationships between these molecules, and they constitute the immunoglobulin superfamily. The two amino terminal, membrane-distal domains of the TCR chains are variable between T cells and constitute a single antigen combining site. The membrane-proximal domains are constant in structure.

Unlike B cell immunoglobulins, conventional TCR cannot interact directly with antigenic epitopes of

proteins, but bind only to short peptides that are derived from protein antigens, and are expressed on the surface of other cells of the body that are known, in this context, as antigen presenting cells (APC). This is because the main function of T cells is to interact with other cells within the context of an immune response: binding to antigenic peptides held on the surface of a cell thereby directs a T cell to exert effects on that particular APC. There are two main functional types of T cells: T helper (Th) cells regulate the activity of other cells of the immune system, whereas T cytotoxic (Tc) cells kill cells that are infected. In order for this to happen, protein antigens that enter the cytoplasm of an APC are processed (i.e. degraded) into peptides, some of which associate with proteins of the major histocompatibility complex (MHC), known in humans as human leukocyte antigens (HLA). The MHC molecule/peptide complexes are then expressed on the surface of the APC where they can interact with T cells whose TCR have combining sites specific for the particular antigenic peptides presented, much in the same way as an Ig combining site interacts with an antigen epitope. This interaction binds the T cell to the surface of the APC thereby enabling these cells to exert effects on each other.

There are two types of MHC molecules called MHC class I and MHC class II (**Figure 11.3**). They have similar three-dimensional structures, but are made up of different types of polypeptide chains. The MHC class I protein is composed of a large alpha-chain noncovalently associated with the smaller beta₂-microglobulin, whereas MHC class II is composed of similarly sized alpha and beta chains. Both class I and class II have two Ig-like domains adjacent to the cell membrane (i.e. they are members of the Ig superfamily), whereas distal to the membrane is the antigen peptide binding cleft. Two alpha-helices form the walls of the cleft and sit on a platform of beta-pleated sheet; antigen peptide is held within the cleft in a linear conformation (rather like a hotdog sausage in a bun!) with its exposed surface available for interaction with a TCR. Peptides of eight or nine amino acids in length can be accommodated within the cleft of MHC class I molecules, whereas the peptides that associate with MHC class II molecules can be between 12 and 20 amino acids in length because they can extend beyond the ends of the peptide binding cleft.

MHC class I molecules present antigens primarily to Tc cells because these cells express a protein called CD8 that binds to the side of the class I alpha-chain when the TCR interacts with the peptide and binding cleft (**Figure 11.3a**). Most tissue cells of the body express MHC class I molecules on their surfaces and thus have the potential to be targets for Tc cells if they become infected by microbes that enter the cytosol, such as viruses. The processing pathway for cytosolic proteins delivers the peptides to MHC class I molecules for binding and presentation. Tc cell clones that specifically bind to these peptides have various ways of

Figure 11.3 Antigen recognition by T cells, see text for details. APC, antigen presenting cell; β_2M , β_2 -microglobulin; C, constant domain; MHC, major histocompatibility complex; Tc, cytotoxic T cell; TCR, T cell receptor; Th, helper T cell; V, variable domain.

killing infected cells by inducing them to undergo apoptosis (programmed cell death):

- the Tc cells secrete two types of proteins stored in cytoplasmic granules: these are perforins that polymerize to form pores through the plasma membranes of the target cells, and granzymes that enter the target cells through the perforin pores and induce apoptosis;
- Fas-ligand expressed on the surface of Tc cells, or tumour necrosis factor (TNF) secreted by Tc cells can induce apoptosis when they bind to their receptors on infected target cells (Fas and TNFR1, respectively).

MHC class II molecules present peptides mainly to Th cells because these cells express the CD4 protein that binds to the side of the class II beta-chain (**Figure 11.3b**). The expression of MHC class II molecules is mainly restricted to cells of the immune system whose functions are to activate, and be activated by, Th cells: these are dendritic cells, macrophages and B cells. These cells deliberately engulf exogenous antigens that, for example, bind to pattern recognition receptors expressed on macrophages and dendritic cells, or specifically bind to the sIg of selected B cell clones. In either case, the surface-bound antigens are endocytosed into membrane-bound vesicles within the cytoplasm. The processing pathway for these vesicular proteins delivers peptides to MHC class II molecules for binding and presentation. Th cell clones that specifically bind to these peptides can then be triggered by the APC to exert their regulatory activities. A range of cell surface and secreted molecules mediate the mutual effects of Th cells and APC on one another. First, there are the interactions of TCR and CD4 with the peptide/MHC class II complex, with the signal resulting from TCR binding being delivered to the interior of T cells by the CD3 protein. Second, a number of other membrane proteins interact between the surfaces of the T cells and

APC to deliver co-stimulatory signals: particularly important are interactions of CD28 with B7, and CD40-ligand with CD40, but others include the interactions of CD2 with LFA-3, and LFA-1 with ICAM (in each case on the T cells and APC, respectively). Third, both the APC and the T cells secrete cytokines as soluble regulatory proteins that bind to specific cell surface receptors. For example, interleukin (IL-1) and IL-12 are important T cell activators secreted by dendritic cells.

When activated, different Th cells preferentially secrete different combinations of cytokines (**Figure 11.4**). Th1 cells produce interferon-gamma (IFN-gamma) that is an important macrophage activator, and IL-2 that stimulates T cells (including Tc cells): thus, Th1 cells induce primarily cell-mediated immunity, although they do also stimulate some antibody production by B cells. Th2 cells produce IL-4, IL-10 and IL-13 that stimulate B cells to produce antibodies, and particularly induce Ig class switching to production of IgE; they also secrete IL-5 that stimulates eosinophils. In addition, Th1 and Th2 cells inhibit each other's activities via the cytokines they secrete. These patterns of type 1 and type 2 cytokine secretion are observed with other cell types, including Tc cells and B cells.

IMMUNITY TO EXTRACELLULAR AND VESICULAR INFECTIOUS AGENTS

Different defence mechanisms are required to deal with infective agents that occupy different compartments within the body. A major distinction is whether an infective agent is in an extracellular environment, or has entered the cytoplasm of cells and so is in an intracellular environment (**Figure 11.5**). This distinction is important because extracellular agents are directly accessible to defensive molecules secreted by cells of the immune

Figure 11.4 Cytokine-mediated regulation by Th1 and Th2 cells. B, B lymphocyte; Eo, eosinophil; IFN-γ, interferon-γ; IL, interleukin; MΦ, macrophage; Tc, cytotoxic T cell; Th1, T helper 1 cell; Th2, T helper 2 cell.

system, whereas intracellular ones are not. Antibodies therefore play a major role in the adaptive immune response to extracellular pathogens (Figure 11.5a).

Antibody effector functions

Antibodies are bifunctional molecules with one end having antigen binding properties while the other end triggers defensive activities. These functional regions are separated by a relatively flexible amino acid sequence between the first and second heavy chain constant domains called the hinge region (Figure 11.2). The two arms containing the antigen combining sites are called the Fragment antigen binding (Fab) regions: each is

Figure 11.5 Immune responses to different types of infections.

composed of a light chain and the variable and first constant domain of a heavy chain. The other constant domains of the two heavy chains constitute the Fragment crystallizable (Fc) region (because it can form crystals when isolated experimentally).

As described under Antigen recognition above, there are five classes of Ig molecules expressed as B cell sIg, four of which are also secreted as antibodies (i.e. IgM, IgG, IgA, IgE, but not IgD). The classes have different heavy chain constant domains, and thus differ primarily in their Fc regions (Table 11.1). The heavy chains of IgG and IgA (and also IgD) each have two constant domains in the Fc region, whereas IgM and IgE have three. In addition, IgM forms pentamers of five Ig monomers held together by a J (joining) chain polypeptide, whereas IgA can similarly form dimers. The large size of IgM means that it is mainly restricted to the bloodstream (except at sites of inflammation), whereas the other classes more readily diffuse into tissues. IgG is the most abundant antibody class and also is transported across the placenta from the maternal to the foetal circulation during gestation. This maternal IgG provides initial protection against infection to newborn babies until their own immune system produces significant levels of antibodies, but is lacking in babies born very prematurely. In its dimeric form, IgA is transported across mucosal epithelia and thus constitutes the main antibody class conferring protection in secretions and at mucosal surfaces. Part of the mucosal receptor that binds and transports IgA across the epithelium remains associated with it as the secretory piece. IgA is also secreted into milk and thus confers protection to the gastrointestinal tract of suckling babies.

Antibodies can neutralize microbes and their toxins simply by binding to them, thereby inhibiting their functions and infectivity. However, antibodies can also contribute to the destruction of infectious agents by interacting with other defensive components, as described below.

Table 11.1 Properties of functional antibody classes and subclasses.

	IgM	IgG1	IgG2	IgG3	IgG4	IgA1	IgE
Molecular weight	970 (pentamer)	146	146	165	146	160 (monomer)	188

Classical complement pathway activation	+ + +	+ +	+	+ + +	—	—	—
Alternative complement pathway activation	—	—	—	—	—	+	—

The complement system

The complement proteins found in the circulation and tissue fluids constitute an important defensive system that can be activated by the Fc regions of IgM and IgG antibodies in what is termed the classical pathway of complement activation (**Figure 11.6**). This is triggered when IgM or several IgG antibodies that are bound to antigen interact with the complement C1 protein complex, resulting in the formation of a C3 convertase enzyme from C4 and C2 (C4b2a). This same C3 convertase can be generated when the pattern recognition molecule mannan-binding lectin (MBL) interacts with mannose residues of microbial surfaces. (MBL is a member of a family of secreted carbohydrate-binding collagenous defensive proteins called collectins.) A different C3 convertase is produced when certain complement proteins directly form a stable complex (C3bBbP) on microbial surfaces in what is termed the alternative pathway of complement activation. IgA can also activate the alternative pathway.

The conversion, or splitting, of complement protein C3 by the C3 convertase enzymes into fragments C3a and C3b is the central event of complement activation and generates a range of biological effects. Some of the C3b can be used to generate more of the alternative pathway C3 convertase; it also modifies the activity of the C3 convertase enzymes to split C5 into C5a and C5b. As mentioned under Innate and adaptive immunity above,

C3a and C5a activate mast cells and thus promote inflammation: they also attract and activate neutrophils (particularly C5a). The C5b fragment forms the membrane attack complex (MAC) with C6, C7, C8 and several molecules of C9: this last complement protein has structural and functional similarities to perforin (see under T cells and antigen presentation above) and forms pores through lipid bilayers. Thus, the MAC has direct antimicrobial effects by disrupting microbial membranes. Finally, in addition to its other activities, C3b opsonizes (i.e. coats) infectious agents, which facilitates their interaction with leukocytes, as described below.

Digestive and inflammatory leukocytes

Some leukocytes have surface receptor proteins that bind to the Fc regions of antibodies (FcR), and others that bind to complement C3b (CR). As described under Innate and adaptive immunity above, the phagocytes (macrophages and neutrophils) express pattern-recognition molecules that enable them to bind microbes directly. However, they also possess FcR specific for IgG or IgA and CR that have particularly high affinities for their respective ligands. Thus, microbes such as bacteria can be firmly bound to the surface of phagocytes when opsonized by antibodies and C3b. This facilitates and activates phagocytosis (i.e. engulfing) of the microbes into

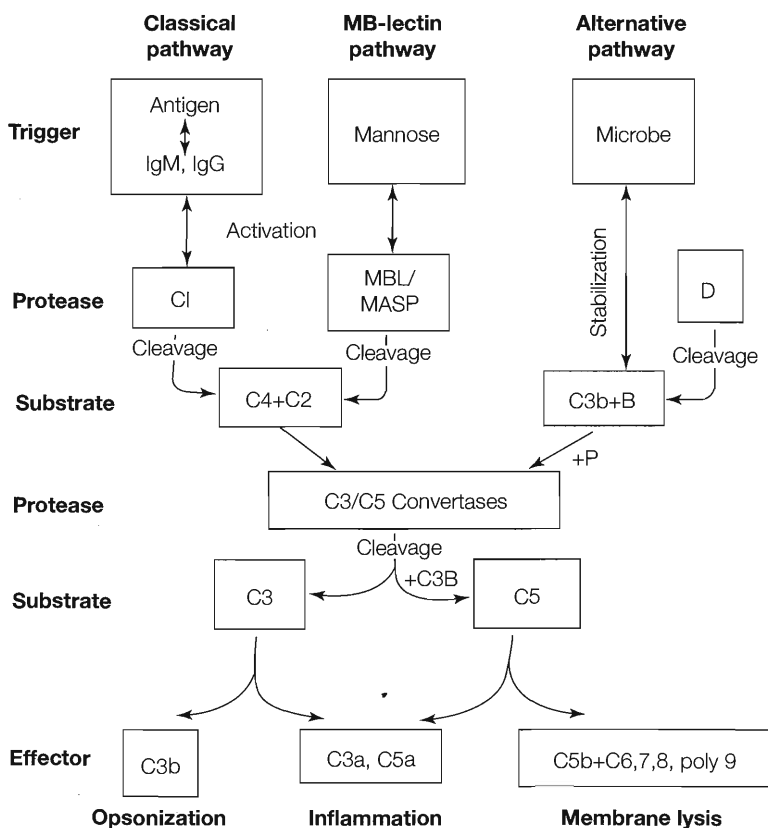

Figure 11.6 Complement activation pathways and effector functions. MBL is mannan-binding lectin; MASP is MBL-associated serine protease. Ig, immunoglobulin; MASP, MBL-associated serine protease; MBL, mannan-binding lectin.

membrane-bound cytoplasmic vesicles. The microbes can then be destroyed by lysosomal enzymes and reactive oxygen molecules.

Some microbes, such as the mycobacteria that cause tuberculosis and leprosy, are relatively resistant to the digestive activities of phagocytes and are able to survive and multiply within the cytoplasmic vesicles of macrophages. In this environment the microbes are protected from the activities of extracellular antibodies and complement proteins. The effective control of such infections is then dependent on the activity of Th1 cells that, as described under T cells and antigen presentation above, produce the potent macrophage activating cytokine IFN- γ : this promotes macrophage digestive activity against microbes in intracellular vesicles (**Figure 11.5b**).

Other infective agents, particularly parasitic worms, such as schistosomes and helminths, are much too large to be engulfed for intracellular digestion by phagocytes. In such circumstances, eosinophils are recruited to undertake extracellular digestion by releasing their digestive proteins (e.g. major basic protein) onto the surface of the parasites. Eosinophils possess FcR (specific for IgG or IgE) and CR, and so again will bind most avidly to opsonized targets.

The other main cells that express FcR for IgE are the tissue mast cells and blood basophils, whose functions are inflammatory rather than directly defensive. These cells are activated when an antigen binds and cross-links several FcR-bound surface IgE molecules. This induces the immediate release of preformed inflammatory mediators, particularly histamine, that are stored in cytoplasmic granules. It also induces the *de novo* synthesis and later release of leukotrienes. (As mentioned above, mast cells are also activated by the complement peptides C3a and C5a.)

IMMUNITY TO CYTOSOLIC INFECTIOUS AGENTS

Some infectious agents actively infect cells by entering the fluid cytosol (**Figure 11.5c**). Viruses are prime examples of such pathogens because they are obliged to infect cells in order to use the machinery of the cells they parasitize in order to replicate themselves. Although antibodies and complement can neutralize viruses while they are outside cells, other immune mechanisms are necessary to deal with intracellular viruses.

An innate mechanism of antiviral defence is the production and secretion of interferon- α (IFN- α) and/or interferon- β (IFN- β) by the infected cells. These type 1 interferons are structurally unrelated to the IFN- γ (type 2 interferon) that is produced by activated T cells and natural killer (NK) cells: however, both types derive their name from their ability to *interfere* with viral replication. Type 1 interferons secreted by

virally infected cells induce an antiviral state in neighbouring noninfected cells by stimulating these cells to produce enzymes that block viral replication. In addition, type 1 interferons enhance MHC class I expression, which is necessary for Tc cell recognition of target cells, and type I interferons activate NK cells. Both these types of killer cells are important in the immune response to intracellular viruses because killing the infected cells inhibits the replication and spread of the virus within the body. NK cells are the first killer cells to be activated and they employ the perforin/granzyme mechanism of cytotoxicity described for Tc cells under T cells and antigen presentation above. However, unlike Tc, NK cells do not possess antigen-specific receptors, but detect abnormalities in the expression of a cell's own surface molecules that may be indicative of the cell being virally infected. NK cells possess two types of receptors that interact with potential target cells – killer activating receptors (KAR) and killer inhibitory receptors (KIR), with the latter providing a dominant inhibitory signal that prevents NK cells from killing normal, uninfected cells. The ligands for KIR are often MHC class I molecules, whose expression may be reduced by viral infection of a cell: this makes the cell susceptible to the activity of NK cells because they then bind predominantly via their KAR.

NK cells also express FcR specific for IgG and so can interact with, and kill, target cells via antibodies that have bound to antigens expressed in the surface membranes of the target cells, as may happen during the formation of budding viruses. This is termed antibody-dependent cellular cytotoxicity (ADCC).

Interferons and NK cells are very important in limiting the replication and spread of a virus during the early stages of an infection, but may not be able to eliminate the infection. The adaptive Tc cells will take longer to be activated, as described under Stages of an immune response above, but can then specifically and efficiently target the infected cells, as described under T cells and antigen presentation above.

INFLAMMATION AND HYPERSENSITIVITY

Inflammatory processes are necessary to recruit components of the immune system to sites of infection. The importance of tissue mast cells as a source of inflammatory mediators has been discussed in previous sections, but many cell types can produce a range of inflammatory mediators, including cytokines and other proteins as well as other types of chemicals (e.g. prostaglandins and leukotrienes). A number of these have particular effects on the vessels that supply blood to infected tissues, promoting vasodilatation, increased vascular permeability, and enhancing endothelial expression of adhesion molecules (particularly selectins and ligands for integrins). The interaction of circulating leukocytes with the

adhesion molecules facilitates their migration across the blood vessel walls and into the infected tissues in response to chemotactic factors.

In addition to localized inflammatory events within infected tissues, systemic effects are induced by cytokines that enter the bloodstream: particularly IL-1, IL-6 and TNF. These have effects on the hypothalamus to induce fever, they promote leukocyte release from the bone marrow, and the release of acute phase proteins from the liver; in particular, the liver-derived pentraxins called C-reactive protein and serum amyloid P possess innate antimicrobial activities.

The enormous destructive potential of the immune system that is unleashed against invading microbes can be equally damaging to the body's own tissues. Thus, during every immune and inflammatory response, a balance must be struck between beneficial and tissue damaging effects. The immune system has evolved regulatory processes to limit the latter but, in some instances, immunological tissue damage becomes the main clinical feature, generating the problems of hypersensitivity.

Allergy and autoimmunity

Tissue damaging adaptive immune mechanisms can be triggered by foreign antigens or the body's own components. The former can be microbes, inducing the immune-mediated tissue damage associated with infective diseases, or can be inert (noninfective) materials that cause allergies. Up to 30 percent of the population is affected by allergies in developed countries, with a host of different allergens affecting different individuals, e.g. pollen, house dust mite, insect venom, food components, latex. On the other hand, reactivity to self-components can lead to autoimmune diseases. Collectively, these affect over 3 percent of the population, with a much higher incidence of subclinical autoimmunity. In organ-specific autoimmunity, the stimulating autoantigens are restricted to particular tissues or organs, e.g. thyroid peroxidase and thyroglobulin in autoimmune thyroiditis, insulin and glutamate decarboxylase in type 1 diabetes mellitus. By contrast, systemic autoimmunity involves reactivity against widely spread tissue components, e.g. DNA, histones and ribonucleoproteins in systemic lupus erythematosus, IgG in rheumatoid arthritis.

Mechanisms of hypersensitivity

Although allergic and autoimmune disorders differ in the nature of the stimulating antigens, they can involve similar mechanisms of tissue damage, referred to as the four mechanisms of hypersensitivity (**Figure 11.7**).

Type I (immediate or reaginic) hypersensitivity occurs in a variety of atopic allergies (**Figure 11.7a**). It involves activation of tissue mast cells when an inducing allergen specifically binds to several IgE antibodies on

the surface of mast cells. The IgE cross-linking induces the release of inflammatory mediators, as described under Digestive and inflammatory leukocytes above, which induce vasodilatation, increased vascular permeability and smooth muscle contraction. For example, inhaled allergens that induce immediate mast cell activation commonly cause allergic rhinitis and extrinsic asthma. These conditions may be seasonal (e.g. hay fever) or perennial in allergies to house dust mite or animal danders, for example. Severe systemic acute forms of type 1 hypersensitivity are seen in anaphylaxis (e.g. to nuts, insect stings, latex).

Type II (cell or membrane reactive) hypersensitivity involves antibodies of the IgG, IgA or IgM classes that bind to antigens associated with cell surface membranes or basement membranes (**Figure 11.7b**). The antigen-bound antibodies then activate complement, which may damage the membranes directly via the membrane attack complex, but also attract and activate neutrophils via the actions of C5a and C3a. The release of digestive enzymes and reactive oxygen species by the neutrophils can then exacerbate the membrane damage. Bullous pemphigoid is an example of a disease involving antibodies to basement membrane antigens. Some of the autoantibodies of pemphigoid bind to hemidesmosomes associated with epidermal basement membranes (although these antibodies have not conclusively been proven to be pathogenic). In pemphigus, by contrast, autoantibodies bind to desmoglein in the epidermal intracellular cement, and clearly correlate with tissue damage. Goodpasture's syndrome is another example of a disease involving autoantibodies to basement membranes; in this case the autoantigen is type IV collagen in alveolar and glomerular basement membranes. The muscle weakness of myasthenia gravis is induced by autoantibodies to the acetylcholine receptors in the post-synaptic membranes of muscles: these antibodies induce complement-mediated damage, receptor internalization and blockade that inhibit neurotransmission by acetylcholine.

Type III (immune complex mediated) hypersensitivity, like type II hypersensitivity, involves IgG, IgA and IgM antibodies, but in this case reacts with soluble antigens to form cross-linked molecular lattices containing multiple antibody and antigen molecules known as immune complexes (**Figure 11.7c**). These complexes can become too large to remain soluble and so precipitate within tissues where they can activate complement and neutrophils, leading to tissue damage. Allergic immune complex disease is exemplified by extrinsic allergic alveolitis that is triggered by inhalation of allergens that form immune complexes in the alveolar walls leading to tissue damage and fibrosis. Common allergens are fungal spores (e.g. in farmers' lung) and animal proteins (e.g. in bird fanciers' lung). In systemic lupus erythematosus, immune complex deposition can occur in various tissues including the skin, joints, lungs, brain and kidneys: these complexes are frequently composed of DNA and

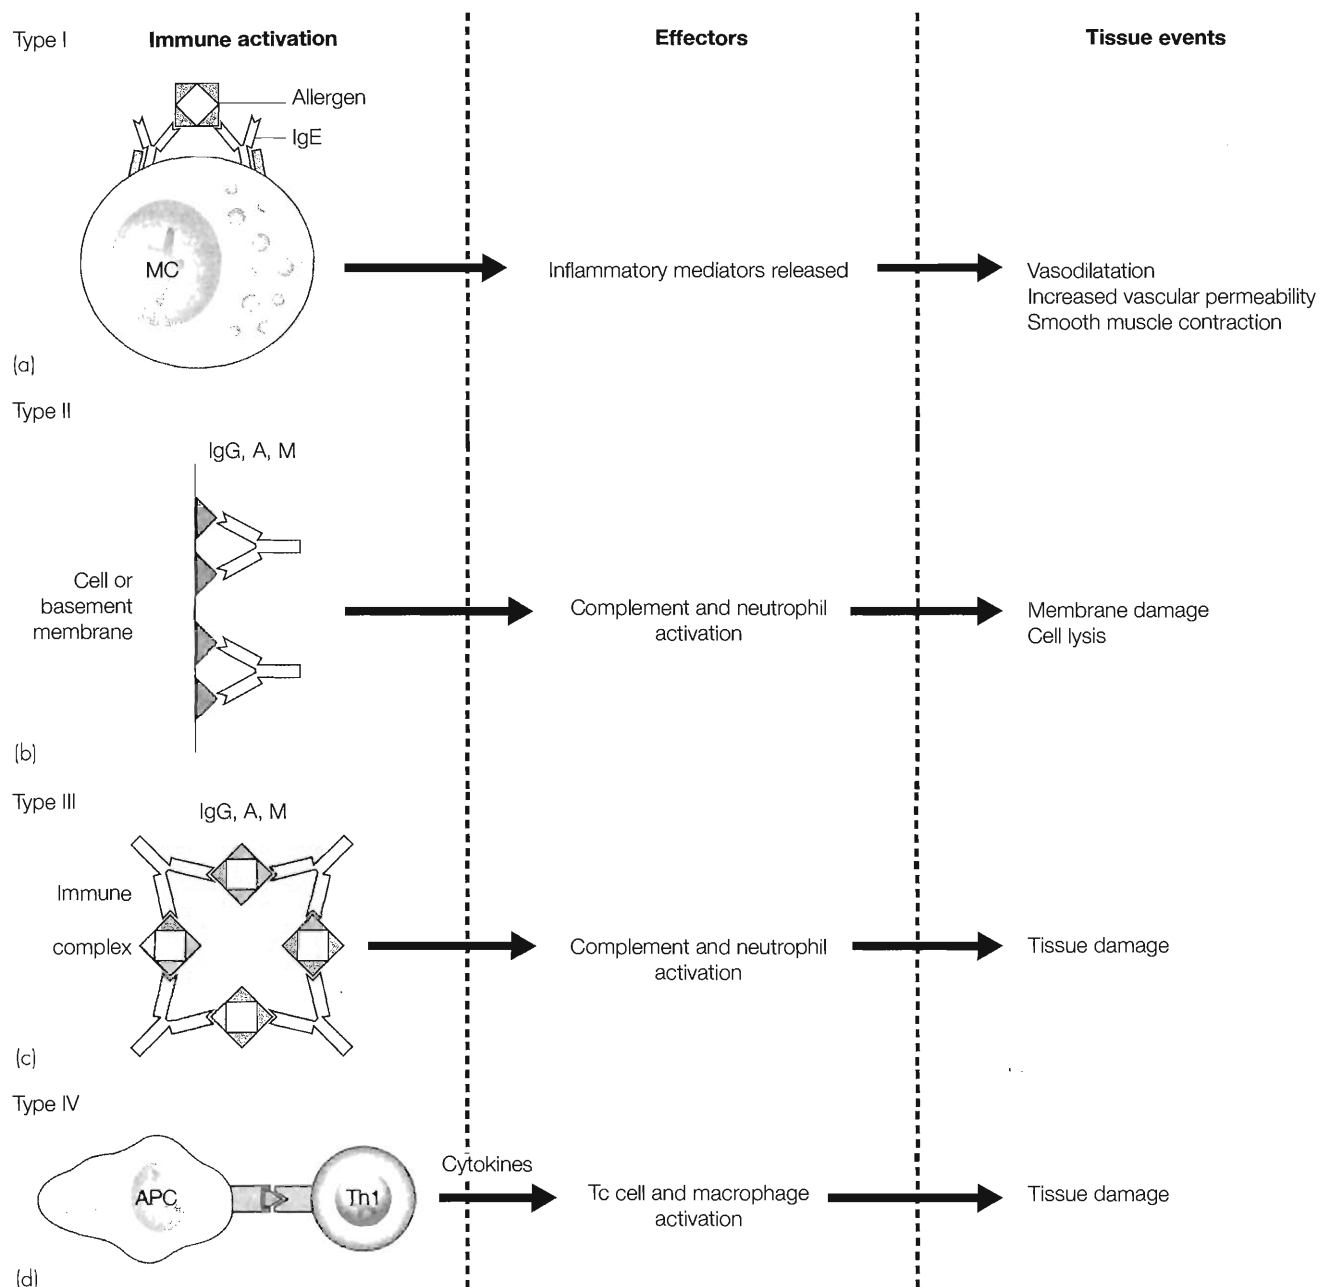

Figure 11.7 Mechanisms of hypersensitivity, see text for details. APC, antigen presenting cell; Ig, immunoglobulin; MC, mast cell; Th1, T helper 1 cell.

anti-DNA antibodies, with contributions from other nuclear and cytoplasmic autoantigens.

Type IV (cell mediated) hypersensitivity is distinguished from the other three types by not involving antibodies. It is principally dependent on the activities of T cell and macrophages with Th1 cells producing cytokines like IL-2 and IFN-gamma that activate cytotoxic T cells and macrophages, respectively (**Figure 11.7d**). Much of the tissue damage in a number of autoimmune diseases is brought about by cell-mediated mechanisms, although autoantibodies are also present, e.g. thyroiditis in the autoimmune thyroid diseases, insulinitis in type 1 diabetes and synovitis in rheumatoid

arthritis. Sjogren's syndrome is characterized by lymphocytic destruction of exocrine tissues, particularly the lacrimal and salivary glands causing dry eyes and mouth. Tuberculosis is an example of an infectious disease in which much of the tissue damage is immune-mediated. Infection of lung macrophages by *Mycobacterium tuberculosis* that is resistant to intracellular digestion leads to chronic T cell activation and cytokine production.

Despite the clinical problems of hypersensitivity diseases, the severe, persistent, unusual and recurrent infection problems associated with the immunodeficiency disorders, described in Chapter 14 Primary

immunodeficiencies, highlight the vital defensive role of the immune system.

The authors searched Pubmed using the key words allergy basic mechanisms, allergic rhinitis mechanisms, allergic rhinitis cytokines, allergic rhinitis chemokines, allergic rhinitis adhesion molecules. Major international allergy journals were also scanned.

INTRODUCTION

Atopy refers to a predisposition to develop exaggerated immunoglobulin E (IgE)-antibody responses against common inhaled aeroallergens. Atopy is defined clinically as a positive skin prick test and/or elevated serum allergen-specific IgE concentration to one or more common inhaled allergens, such as grass pollen, cat hair or house dust mite (HDM). Whereas a high proportion of atopic individuals develop allergic manifestations at some time during their lifetime, a substantial minority remain asymptomatic. In contrast to atopy, the term 'allergy' refers to the clinical expression of atopic allergic disease, such as allergic rhinitis, allergic bronchial asthma, atopic eczema and IgE-mediated food allergy.

In this chapter, the aetiology of allergic disease is briefly considered in relation to genetics and to environmental influences. Pathogenesis is considered, particularly in relation to allergic rhinitis, and considers mediators, IgE antibody, effector cells, mechanisms of cell recruitment, the role of T cells and T-B cell interactions, including local IgE regulation at allergic tissue sites and the role of IgE in facilitating allergen presentation to T cells. The influence of topical nasal corticosteroids and

allergen injection immunotherapy on these events are compared and contrasted.

A better understanding of basic mechanisms of allergy and the influence of current treatments has given rise to a number of novel, more targeted therapies for allergic rhinitis and asthma. New strategies for allergen immunotherapy are also briefly considered. Currently available tests for allergy diagnosis, including skin prick tests, allergen specific IgE concentrations and the role of serum tryptase measurements, are presented.

AETIOLOGY

Genetics

Allergic diseases result from a complex interaction between genetic and environmental influences. The contribution of genetics was illustrated by twin studies in which a higher concordance rate for atopy and allergic diseases was found in monozygotic compared with dizygotic twins.^{1, 2} Over the past 15 years, two approaches have been used to identify disease-causing genes.³ One

approach, entitled positional cloning, is based on the presence of highly polymorphic genetic markers with positions on a chromosome that are known. When multiple families are analysed, markers close to the disease gene will statistically be coinherited with the disease. Candidate gene approaches consist of directly studying a narrow region of the genome around the suspected gene with highly polymorphic markers. Interpretation of these studies has been complicated by variability in the strict definition of the clinical phenotypes within atopy, allergy and asthma. Nonetheless, multiple genetic loci have been identified. Examples,³ classified according to their chromosomal localization, are given in **Table 12.1**. All of these genes have biologic functions consistent with a role in the pathogenesis of allergic disorders. Chromosome 5q is of particular interest, representing the loci of the major T helper (Th) lymphocyte 2 cytokine genes,⁴ leukotriene C4 synthase (LTC4-S), the β -adrenergic receptor and the glucocorticosteroid receptor. A recent study which combined positional cloning techniques with candidate gene analysis identified strong linkage between asthma and bronchial hyperresponsiveness with the gene for A disintegrin and metalloprotease 33 κ (ADAM-33), a cell surface protease which is part of the matrix metalloproteinase family, considered important in remodelling responses in the basement membrane to damaged epithelium and airway smooth muscle.⁵

Environment

ALLERGENS

The major allergens giving rise to allergic rhinitis and asthma are listed in **Table 12.2**. Within the UK, seasonal exposure to grass pollens is a major cause. In recent years, tree pollens that give rise to springtime hay fever have

Table 12.2 Inhaled allergens.

Seasonal	Perennial	Occupational
Grasses	Housedust mite	HMW: laboratory animals, flour, latex
Trees	Cats	LMW: colophony, isocyanates, acid anhydrides
Weeds	Dogs	
Moulds	Horses	

become more prominent. Birch pollen allergy is commonly associated with oral allergy syndrome. Allergenic cross reactivity exists between birch pollen and apple, stone fruits and hazelnut, all of which may give rise to itching and swelling in the lips, mouth and pharynx. The common perennial allergens are house dust mite and animal danders. An occupational cause should be suspected in all patients whose symptoms are worse within the workplace or during the evening following work, with improvement at weekends and/or during holiday periods. Allergy to high molecular weight (HMW) allergens, including laboratory animals and latex, is commonly associated with rhinitis. In contrast, associations of rhinitis with exposure to low molecular weight (LMW) agents, such as isocyanates and acid anhydrides that are used as catalysts in paint and resin systems, are less well characterized. Further studies are needed.

HYGIENE HYPOTHESIS

There has been a marked increase in allergic disorders over the last 20 years in developed countries, including Western Europe, Australia, and New Zealand, where approximately 20 percent of the population have allergic rhinitis. Increases over such a short time period cannot be explained by genetic influences. Suggestions have included increases in allergen exposure due to changes in modern housing, such as fitted carpets, central heating and double glazing, which may have increased exposure to mite allergens. Other possible influences are increases in environmental pollution, and changes in the diet and the gut flora. Strachan coined the term 'hygiene hypothesis' which suggested that improved hygiene in industrialized societies, together with improved public health measures and use of vaccines and antibiotics, have reduced the incidence of infections.⁶ Epidemiologic studies have shown that large family size, and presumed high exposure to infectious agents, protects against the development of allergic diseases. Similarly, exposure to farm animals early in life reduces atopic sensitization and asthma, possibly due to higher bacterial endotoxin levels.⁷ The hypothesis is that lack of infections leads to less frequent stimulation of Th1-biased responses, thereby facilitating development of Th2-biased immune

responses to environmental allergens.⁸ However, the observed parallel increases in Th1-mediated autoimmune disorders, such as type-1 diabetes and multiple sclerosis, argue against this theory.⁹ An alternative explanation that may possibly account for the observed increase in both Th1 and Th2 disorders in recent years is a failure of regulation of the immune response by so-called T regulatory cells that secrete the inhibitory cytokines interleukin (IL)-10 and transforming growth factor (TGF)- β . Since regulatory T cells control immune responses to bacteria, a reduced microbial pressure could suppress the development or function of T regulatory cells, which would have an impact on both allergic and autoimmune diseases.¹⁰ Similar hypotheses underpin the mechanism of allergen specific immunotherapy, the only treatment which has been shown to modify the natural history of allergic disorders (see Allergen injection immunotherapy).

POLLUTION

It has been suggested that urban pollution, particularly from motor exhaust fumes, may be one factor responsible for the increasing prevalence of allergic disorders. For example, the increase in hay fever due to Japanese cedar pollen over the last 30 years has coincided with a dramatic increase in motor vehicle exhaust pollution. The increase in cedar pollen allergy in Japan is largely confined to urban, rather than rural, areas.¹¹ Diesel particulates have been shown to be adjuvant for IgE antibody production, whereas exposure to the combination of nitrogen dioxide and ozone may amplify subsequent pollen-induced immediate symptoms of rhinitis. However, studies comparing the prevalence of hay fever in heavily polluted districts in Leipzig compared with relative pollution-free areas of Munich¹² have shown that hay fever is more common in Munich. For these reasons, the role of pollution in hay fever and asthma remains controversial. Undoubtedly, pollutants may irritate or exacerbate symptoms, although the role of specific

pollutants in the development of pollen sensitivity and the persistence of hay fever symptoms remains in doubt.

PATHOGENESIS

Early and late allergic responses

The classic features of allergic inflammation include IgE-dependent activation of mast cells and tissue eosinophilia (**Figure 12.1**).¹³ Following allergen provocation in sensitive subjects, there occurs an early allergic response that is maximal at 10–30 minutes and resolves within one to two hours. In the skin, this is manifest as a weal and flare response, in the nose as itching that occurs within seconds and watery nasal discharge and nasal congestion within minutes, whereas allergen inhalation results in immediate bronchospasm with associated wheezing, cough and chest tightness. In a proportion of subjects, approximately 50 percent of adults and 70 percent of children, there occurs a late phase response that begins at three to four hours, is maximal at 6–12 hours and resolves within 24–48 hours. The magnitude of early and late phase responses is dependent upon the sensitivity of the subject and the allergen dose used for provocation. In the nose, late responses are manifest largely as nasal obstruction and are far less pronounced than the airways hyperinflation, chest tightness and dyspnoea that accompany late asthmatic responses. Late asthmatic responses are accompanied by an increase in nonspecific bronchial hyperresponsiveness that may last for several days, or occasionally weeks, following a single allergen provocation. During this time, there is a heightened sensitivity to nonspecific triggers such as exercise, cold air and viral infections, and a reduced threshold for development of immediate allergic responses following allergen re-exposure.¹⁴

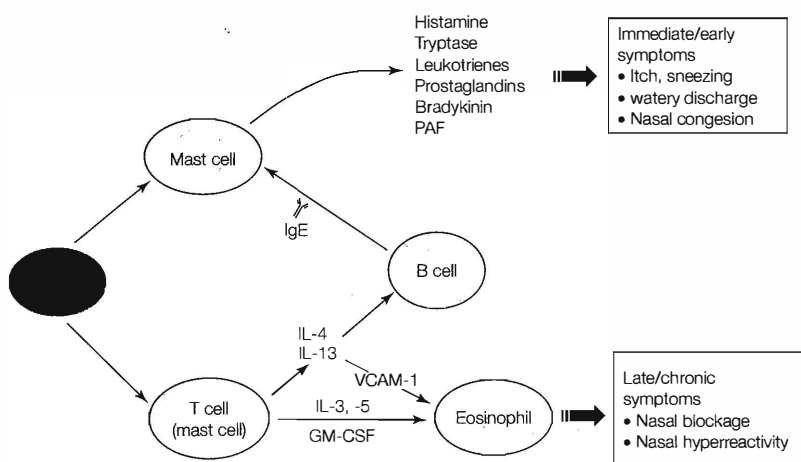

Figure 12.1 Basic mechanisms of human early and late allergic responses.

Mediators of hypersensitivity

The early allergic response is largely mast cell-dependent. Cross linking of adjacent IgE molecules on the mast cell surface by allergen results in mast cell degranulation and the release of mediators of hypersensitivity with known biological properties responsible for the early allergic response. Mediators released by the mast cell include histamine, leukotriene C₄, D₄ and E₄ and tryptase.^{15, 16}

Histamine stimulates H₁ receptors on sensory nerves giving rise to immediate itching and sneezing within seconds of allergen exposure. In addition, histamine causes vascular dilatation and increased permeability with plasma exudation, contributing to the sensation of nasal congestion. Histamine may also provoke immediate bronchospasm and is responsible for most, but not all, the immediate skin weal and flare.

Leukotrienes increase vascular permeability, induce mucus secretion from nasal and bronchial glands and induce bronchoconstriction involving, in particular, the small airways. Whereas histamine and tryptase are preformed in mast cell granules, leukotrienes and the mast cell derived prostaglandin D₂ are newly formed,

membrane-derived mediators generated from membrane arachidonic acid under the influence of 5-lipoxygenase. The role of tryptase is unclear, although tryptase has potent enzymatic activity and breaks down kininogen from the blood, leading to the formation of potent inflammatory kinins, including bradykinin, an extremely potent mediator that promotes acute plasma extravasation and is likely to be a major factor in the formation of angio-oedema. In addition, mast cells and basophils produce IL-4 and other inflammatory cytokines that may contribute to the induction of late responses.

In contrast to the immediate response, the late phase response is characterized by T cell recruitment and activation and tissue eosinophilia (**Figure 12.1**).¹⁶ Whereas mast cells and basophils are recognized sources of IL-4 and IL-13, T lymphocytes represent the principle source of Th₂ cytokines during late responses.¹⁷ Examples of mast cells, activated (EG²⁺) eosinophils, cluster of differentiation (CD)⁴⁺ T cells and IL-5 messenger ribonucleic acid (mRNA)⁺ cells present within the nasal epithelium and submucosa are shown in **Figure 12.2**.

Figure 12.2 Immunohistochemistry and *in situ* hybridization studies demonstrating labelling of (a) mast cells, (b) activated eosinophils, (c) Th lymphocytes and (d) cells expressing mRNA for the cytokine IL-5.

Sensory nerves

Activation of sensory nerves is a pivotal event in the generation of acute symptoms of rhinitis.¹⁸ Also, sensory innervation is, in large part, responsible for increased nasal hyperreactivity to nonspecific triggers in allergic individuals. For example, capsaicin is a potent stimulus for nerve C-fibres and provokes a 100-fold stronger secretory response in patients with allergic rhinitis compared to healthy control subjects following allergen challenge. Sensory nerves themselves may produce inflammation by an antidromic axon reflex which causes sensory nerves to release neuropeptides such as substance P and neurokinin A. This 'neurogenic inflammation' is self-perpetuating and represents an important component of the allergen-IgE interaction. Nerve growth factor, responsible for maturation and development of sensory nerves, is present in nasal fluids of patients with chronic allergic rhinitis and is increased after allergen challenge.¹⁸ Thus, the immediate response represents a complex interaction between mediators of hypersensitivity released following mast cell activation and their interaction with sensory nerves, the vasculature and mucus-secreting glands. Increased allergen-induced target organ hyperresponsiveness that is associated with late responses and ongoing day-to-day allergic disease is likely to relate to a combination of both inflammation and heightened sensory nerve activation, the contribution of these components varying in different individuals.

Immunoglobulin E

The concentration of IgE in serum is the lowest of the five immunoglobulin classes, being around 100–400 ng/mL. The majority of IgE is tissue-bound with a half-life of approximately 11–14 days. IgE is bound to high affinity receptors (Fcε R1) on mast cells and basophils.¹⁹ Recent studies have demonstrated that, in contrast to other immunoglobulins, Fcε R1 is present on dendritic cells in atopic individuals and in low numbers on monocytes/macrophages and eosinophils, although on these cell types, Fcε R1 lacks the β-chain subunit and is of doubtful functional significance, at least in terms of IgE-dependent activation.²⁰ IgE is also bound to low-affinity IgE receptors Fcε R2 (CD23) present on monocytes/macrophages and, in particular, on B cells.

B lymphocytes initially produce IgM antibodies. Heavy chain class switching in favour of IgE antibody production occurs in two steps.²¹ Step one involves generation of a sterile ε-germline gene transcript under the influence of IL-4 and/or IL-13. Step two, heavy chain gene rearrangement, will only proceed following cross-linking of CD40 on the B cell surface by CD40 ligand. Th2 T-lymphocytes express IL-4, IL-13 and CD40 ligand and are essential for allergen-specific class switching in to IgE synthesis.

Additionally, mast cells and basophils express IL-4, IL-13 and CD40 ligand and therefore have the potential to augment/amplify IgE synthesis in a nonspecific manner.

The traditional view has been that IgE class switching occurs in the bone marrow and draining regional lymph nodes. However, the presence of Th2 cells and B cells and the expression locally of IL-4 and IL-13 in the nasal and bronchial mucosa raised the possibility that IgE synthesis might occur locally at these allergic tissue sites. In support of this concept, CD20⁺ B cells that express ε germline transcripts and Cε heavy chain RNA are detectable in the nasal mucosa in allergic rhinitis²² and in the bronchial mucosa of patients with both atopic and nonatopic asthma.²³ Local increases in allergen-specific isotype-specific IgE are detectable in bronchoalveolar lavage fluid following allergen challenge in atopic asthma.²⁴ Coker and colleagues identified and sequenced IgE variable region heavy chain genes from B cells within the nasal mucosa.²⁴ In contrast to findings in peripheral blood, the detection of highly homologous variable segment genes within the nasal mucosa confirmed the clonality of local B cells, consistent with heavy chain class switching occurring within the nasal mucosa. By use of *in situ* hybridization of sections of cultured nasal mucosal biopsies, upregulation of IL-4 and ε germline gene transcripts were detectable within 24 hours of allergen stimulation.²⁵ By use of enzyme-linked immunosorbent assay (ELISA) of supernatants from cultured nasal biopsies, spontaneous synthesis of IgE protein was detectable at three to seven days.²⁶

Taken together, these observations confirm local synthesis of IgE within the respiratory mucosa, thereby providing a long-lived source of IgE for local sensitization of mast cells and basophils in target organs. This may explain why some atopic individuals with elevated serum IgE concentrations develop rhinitis, whereas others develop bronchial asthma or atopic eczema, whereas others may exhibit positive skin prick tests without any clinical manifestations. The presence of IgE in the bronchial mucosa of nonatopic asthmatics and, as recently shown in the nasal mucosa of patients with so-called intrinsic rhinitis,²⁷ implies the potential importance of IgE in these subjects in the absence of positive skin prick tests or raised serum allergen-specific IgE concentrations. The findings raise the testable hypothesis that strategies directed against IgE may also be of value in patients with late onset 'intrinsic' rhinitis and asthma.

Effector cells

MAST CELLS

Mast cells are tissue-based inflammatory cells derived from cKIT⁺ CD34⁺ pluripotent bone marrow stem cells. Mast cell precursors circulate via the blood and lymphatic tissues where they mature under the influence of cKIT-ligand

(stem cell factor (SCF)), produced from local structural cells.¹⁹ Other cytokines involved in mast cell maturation and survival include IL-4, IL-5, IL-6, IL-9 and interferon gamma (IFN- γ). Mast cells have been classified traditionally as mucosal and connective tissue types. By use of specific immunostaining, mucosal mast cells are predominantly tryptase-only positive, whereas connective tissue mast cells are tryptase positive chymase positive. Although this classification has been questioned, there is clear evidence for a predominance of tryptase only-positive mast cells in the bronchial mucosa, and in patients with hayfever, natural allergen exposure results in transepithelial migration of tryptase-only positive mast cells to the epithelial surface.

BASOPHILS

Basophils are granulocytes that share many common features with mast cells, including expression of Fc ϵ R1, metachromatic staining and the synthesis and release of histamine, and IL-4.¹⁹ Basophils develop from CD34⁺ pluripotent bone marrow stem cells which circulate to the periphery where IL-3 is the dominant cytokine involved in differentiation of basophils from IL-3-receptor positive precursors. The role of basophils in allergic disease has recently been highlighted following the availability of two basophil granule-specific monoclonal antibody markers, namely BB-1 and 2D7. Basophils are increased in the nasal epithelium during seasonal grass pollen exposure and eliminated following successful immunotherapy. Basophils are detectable in the bronchial mucosa in asthma, and they increase in numbers and express IL-4 during allergen-induced late responses.²⁸

EOSINOPHILS

Blood and tissue eosinophilia are hallmarks of allergy.¹⁹ Eosinophils have a bilobed nucleus and multiple intracellular granules that contain highly basic proteins that include major basic protein (MBP) and eosinophil cationic protein (ECP). Eosinophils are derived from progenitors in the bone marrow under the influence of IL-3, IL-5 and granulocyte-macrophage colony stimulating factor. Eosinophils are present at allergic tissue sites and increase in numbers following allergen provocation¹⁶ and during natural seasonal exposure. Eosinophil proteins have been localized to sites of epithelial damage in asthma and have been shown to be highly toxic *in vitro* to human bronchial epithelium. Eosinophils produce lipid mediators, including leukotriene C4 and platelet activating factor (PAF). They also produce a range of cytokines, including IL-4, IL-5 and granulocyte-macrophage colony stimulating factor (GM-CSF). Eosinophils have many surface receptors, including IL-3R, IL-5R and GM-CSFR. Characteristic chemokine receptors (CCR) include CCR3. They possess immunoglobulin receptors including Fc γ 2

(CD32), Fc α R1 (secretory IgA), complement receptors (C3aR, C5aR) and adhesion molecules, particularly very late antigen (VLA)-4, the ligand for the eosinophil-selective vascular cell adhesion molecule-1 (VCAM-1).

CELLULAR RECRUITMENT

The presence of effector cells in allergic inflammation depends upon a balance between their recruitment, persistence and survival in tissues. Local mechanisms responsible for recruitment and activation of eosinophils are shown in **Figure 12.3**. Eosinophil recruitment is an active process involving four steps. Mast cell activation by allergen results in the release of inflammatory cytokines including IL-1 and tumour necrosis factor (TNF)-alpha that upregulate adhesion molecules present on the vascular endothelium. The transit of eosinophils is initially slowed by the early expression of E-selectin which binds to its ligand present on the eosinophil surface.²⁹ This results in the rolling of the eosinophil along the vascular endothelium. Cell activation with an increase in eosinophil surface expression of receptors such as CCR3 and VLA-4 occurs in response to chemokines, particularly eotaxin and RANTES (released from activated normal T cells expressed and secreted).³⁰ The adhesion of eosinophils to the vascular endothelium is dependent upon binding of VCAM-1 produced from the vascular endothelium to its ligand VLA-4 on the eosinophil surface.

Following adhesion, there follows the active migration of eosinophils through the vascular endothelium, followed by directional migration along a chemotactic gradient involving interaction between eotaxin and RANTES with CCR3. Other chemotactic factors, which may be involved in eosinophil recruitment, include the monocyte chemotactic proteins (MCP)-2, and 3. CCR3 is a common receptor for eotaxin, RANTES, and the monocyte chemokine proteins and is highly expressed on the surface of eosinophils, basophils, mast cells and Th2 T-lymphocytes, all of which are characteristic of allergic inflammation. Nasal administration of both RANTES³¹ and eotaxin³² has been shown to provoke nasal symptoms and increase local eosinophils. Both eotaxin³³ and RANTES are detectable in nasal lavage fluid and/or the nasal mucosa during natural disease and increase following allergen provocation.³⁴

T-LYMPHOCYTES

T-lymphocytes are central to the pathogenesis of allergic diseases, since they are the only cells capable of recognizing antigenic material after processing by antigen presenting cells. T-cell responses are classified into two subtypes, depending on their cytokine profile in response to antigenic stimulation. Th1 cells express predominantly IFN- γ and IL-2, whereas Th2 cells express preferentially IL-4, IL-5 and IL-13.³⁵ Present evidence points to the

Figure 12.3 Schematic showing eosinophil recruitment from the vascular compartment to the tissues demonstrating the complex interplay between vascular adhesion molecules and chemokines.

recruitment of Th2 cells, their activation in tissues and generation of Th2 cytokines as cardinal features of both allergic rhinitis and asthma.³⁶ Allergenic peptides are presented to T-cell receptors as a high-affinity complex of peptide and major histocompatibility complex (MHC) class II molecules. The binding of peptide alone to the T cell receptor (TCR) is insufficient to cause activation of T cells in the absence of costimulation. Costimulatory molecules involved include CD4, CD8, lymphocyte-function associated (LFA)-1, CD28 and cytotoxic T-lymphocyte-associated molecule (CTLA)-4 on the T-cell and MHC class II, intercellular adhesion molecule (ICAM)-1 and -2, and the B7 homologues, CD80/CD86 on the antigen presenting cell surface. In particular, CD28 ligation by B7-1 (CD80) and B7-2 (CD86) is a necessary requirement for the synthesis and secretion of the T-cell growth factor IL-2. In the absence of co-stimulation, signalling through the TCR results in a nonresponsive state known as 'anergy', which may last for several days or weeks.³⁷

T cells may differentiate preferentially into Th1- or Th2-cells, depending on their location, the level (or dose)

of allergen stimulation, the nature of the antigen presenting cell, the level of co-stimulation and the local cytokine environment.³⁶ In general, low doses of soluble allergen presented at mucosal surfaces by B cells or dendritic cells, preferentially favour Th2 T cell development. These circumstances are typical of those occurring during natural seasonal pollen exposure and in the presence of low doses of perennial environmental allergens, such as cat fur and house dust mite. In contrast, high concentrations of allergen via injection as, for example, during allergen immunotherapy, and preferential presentation by monocyte/macrophages favour Th1 T lymphocyte development. The local cytokine milieu is a critical factor in T lymphocyte differentiation and activation. For example, IL-4 produced by mast cells and basophils, as well as T-lymphocytes³⁸ may induce Th2 T lymphocyte development at mucosal surfaces, whereas local IL-12 may induce preferential Th1 responses. An additional level of control of T-cell activation during IgE-dependent responses occurs at the level of the antigen presenting cell (APC). Allergen-specific IgE bound to inhaled allergens can be taken up

and presented to T cells via low affinity IgE receptors (CD23 Fcε R2) expressed on B cells and other APCs or via high affinity IgE receptors (Fcε R1) expressed on monocytes or dendritic cells.³⁹ Formation of allergen–IgE complexes, with preferential uptake at low allergen concentration, as occurs at mucosal surfaces, results in a marked (10–100-fold) reduction in threshold levels of aeroallergen necessary to trigger T cell activation *in vivo*. Thus *in vivo* T cell-dependent late responses may be augmented by IgE-dependent mechanisms, including IL-4 and formation of allergen–IgE complexes. Conversely, interference with these IgE-dependent mechanisms by ‘functional’ immunoglobulin G (IgG) antibodies (see Allergen injection immunotherapy) may down-regulate antigen-specific T-cell responses, manifest as inhibition of late responses *in vivo*.⁴⁰

Preferential Th1 or Th2 T-lymphocyte activation and cytokine synthesis is dependent on interactions between sequence-specific transcription factors, present within the cytoplasm of T cells that may translocate to the nucleus and interact with promotor and enhancer regions of RNA polymerase II-dependent genes.⁴¹ For example, IL-4 signalling in favour of Th2 T lymphocyte development requires activation of the signal transducer and activator of transcription (STAT)-6. Th2 cytokine synthesis is dependent upon the transcription factors c-MAF (critical for the expression of IL-4) and GATA-3 (involved in the regulation of both IL-4 and IL-5). Conversely, IL-12-induced Th1 T lymphocyte development requires activation of STAT-4 and synthesis of the Th1 cytokine INF-γ is critically dependent upon the transcription factor T-bet.

Recent evidence from murine models points to an additional distinct subset of so-called T-regulatory cells which are capable of inhibiting the activation of T cells at peripheral sites.⁴² These T cells are CD4⁺ CD25⁺, and their immunosuppressive properties have been linked to the production of the cytokines IL-10, TGF-β or both. Regulatory T cells might also down-regulate T-cell responses through cell–cell contact, as well as through the direct effect of these cytokines.⁴³ In man, IL-10 producing CD4⁺ CD25⁺ T regulatory cells have recently been recognized in peripheral blood⁴⁴ and have been shown to play a role in natural tolerance induction in bee keepers during high allergen exposure to bee venom.⁴⁵ T-regulatory cells have been associated with the co-expression of certain cell surface markers such as GITR and CTLA-4. The novel transcription factor Fox P3 has been shown to be important in gene regulation of IL-10 synthesis in these cells.

Over the last decade, studies in peripheral blood, the nose and the lung have confirmed the central role of Th2 T lymphocytes in allergic diseases. Th2 cytokines are detectable in the nasal mucosa during seasonal and perennial rhinitis. Following local allergen provocation, preferential T lymphocyte expression of IL-4 and IL-5, but not INF-γ, is detectable in bronchoalveolar lavage, the bronchial mucosa and in the nose (Figures 12.4 and

12.5).¹⁷ The combination of immunocytochemistry and *in situ* hybridization has co-localized the majority of Th2 cytokines detectable at 24 hours after allergen to T-lymphocytes, whereas at earlier time points, mast cells (IL-4) and eosinophils (IL-4 and IL-5) are more prominent sources of Th2 cytokines.⁴⁶ Th2-lymphocytes preferentially express the chemokine receptors CCR3, CCR4 and CCR8, all of which may be involved in their recruitment and activation in allergic rhinitis and asthma.³⁰

DENDRITIC CELLS

Dendritic cells are professional antigen presenting cells which are abundant within the epithelium and submucosa of the upper and lower respiratory mucosa in patients with allergic diseases.⁴⁷ Expression of CD1a on the cell surface is a marker of a subclass of dendritic cells, Langerhans cells. Traditionally, dendritic cells have been classified as myeloid derived DC1 cells derived from human blood monocytes or DC2, plasmacytoid cells derived from lymphoid cells. Dendritic cells are highly efficient at capturing, processing and presenting antigen to T cells. It has been suggested that DC1 cells produce high levels of IL-12 and favour Th1 T-cell development, whereas DC2 cells are low-IL-12 producers and support preferential Th2 T-lymphocyte differentiation. However, it is likely that rather than distinct dendritic cell subpopulations, differential function may depend on their location, their degree of maturation and the local cytokine milieu. Immature cells express high levels of immunoglobulin receptors and are highly endocytic, in keeping with efficient allergen capture. In contrast, mature cells express high levels of MHC class II and have upregulated CD86 expression and produce abundant cytokines, features consistent with their role in allergen presentation and immune modulation. A recent study in rodents suggested that local allergen provocation in the bronchial mucosa resulted in the rapid maturation from immature to mature phenotype of dendritic cells within two hours of allergen exposure, with rapid upregulation of MHC class II and upregulated CD86 expression.⁴⁸ Interestingly, this rapid maturation was only observed in dendritic cells within the bronchial mucosa and not peripheral lung. Rapid dendritic cell recruitment to the bronchial mucosa in atopic asthmatic patients has also been observed within the time frame of late asthmatic responses following local segmental allergen challenge. Recruitment of so-called plasmacytoid (CD123) IL-3R α-chain positive, CD45 RA positive cells increase dramatically in numbers, as detected in nasal biopsies, following local allergen challenge repeated daily for seven days.⁴⁹ This is of particular interest since plasmacytoid dendritic cells matured *in vitro* can induce preferential Th2 T-cell development. Recently, Novak examined IgE receptor expression on dendritic cells

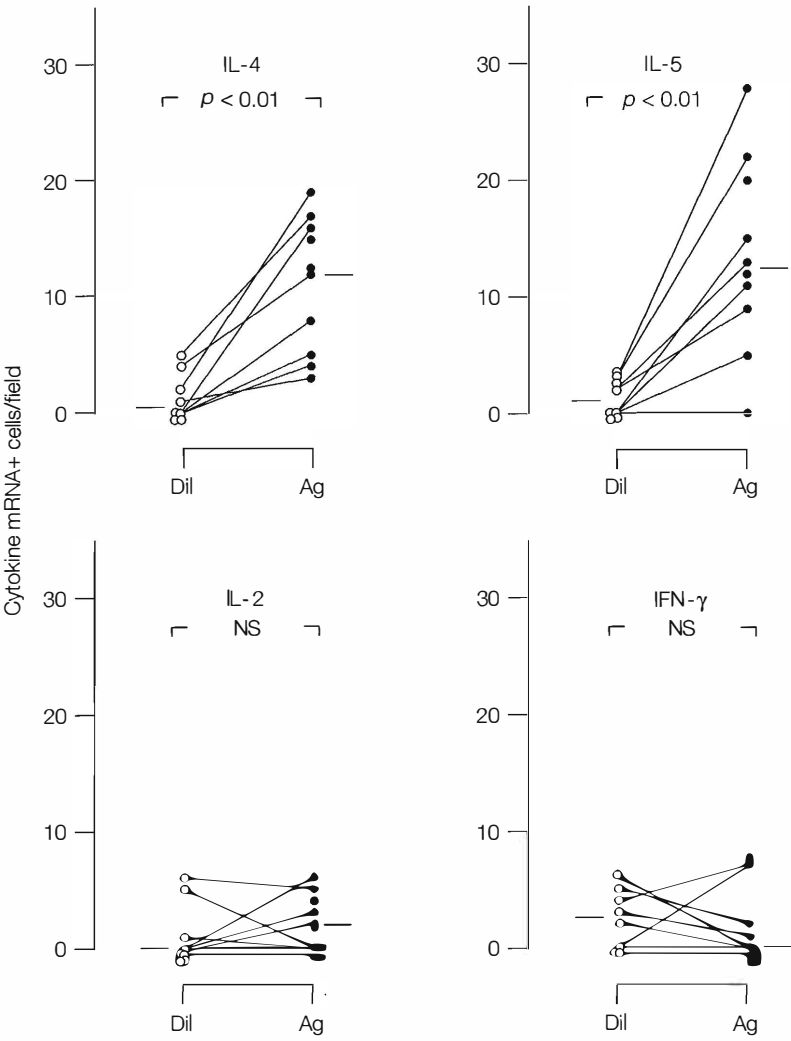

Figure 12.4 Preferential production of Th2 type cytokines, detected by *in situ* hybridization during allergen induced late responses in the nasal mucosa.

Figure 12.5 The pivotal role of Th2 lymphocytes and the cytokines IL-4 and IL-5 in the pathogenesis of the allergic response.

from atopic and nonatopic individuals. Fc ϵ R1 α is expressed on dendritic cells from both groups, but differential expression of the gamma chain on dendritic cells from atopics is associated with sustained surface expression of Fc ϵ R1, consistent with a more efficient antigen-presenting cell in the context of IgE-associated Th2 T-lymphocyte development.⁵⁰

INFLUENCE OF TREATMENT

Antihistamines

Antihistamines are effective in the partial suppression of immediate allergen-induced responses in the skin, nose and lung. The particular importance of histamine as an

inflammatory mediator in the upper airway is confirmed by the effectiveness of antihistamines in allergic rhinitis, whereas antihistamines have little or no effect on allergen-induced late asthmatic responses and are much less effective in bronchial asthma. In contrast, topical corticosteroids, the most effective agents in the treatment of chronic perennial allergic rhinitis and asthma, when given immediately before allergen provocation, have virtually no effect on allergen-induced early responses. In contrast, topical corticosteroids, when given immediately before challenge, are highly effective in inhibiting allergen-induced late responses in the skin, nose and lung. For example, in a controlled trial in patients with allergic asthma, inhaled beclomethasone, but not oral cetirizine, was effective in suppressing allergen-induced late asthmatic responses and associated increases in airway methacholine responsiveness.⁵¹ [****] Similarly, in a controlled trial in patients with allergic rhinitis, six weeks treatment with intranasal aqueous fluticasone propionate resulted in only a 50 percent inhibition of early nasal symptoms whereas complete inhibition of nasal symptoms at 1–24 hours after challenge was observed.⁵² [****] These effects of corticosteroids *in vivo*, are consistent with their observed effects *in vitro*. Corticosteroids have no effect on IgE-dependent activation of mast cells and mediator release *in vitro*, whereas allergen-induced Th2 T-lymphocyte proliferation and cytokine secretion are exquisitely sensitive to corticosteroids in low 10^{-10} to 10^{-8} molar concentrations.⁵³ [****]

Topical corticosteroids

Topical corticosteroids and their effects on inflammatory cells, antigen presenting cells, cytokine synthesis and the expression of chemokines and adhesion molecules have been extensively studied in allergic rhinitis following allergen provocation and during natural seasonal exposure. For example, six weeks treatment with topical fluticasone propionate resulted in a marked reduction in T lymphocytes, eosinophils and mast cells within the nasal mucosa.⁵² [****] Effects were more pronounced on cell numbers in the epithelium compared to the lamina propria and submucosa. Neutrophil numbers were either unaffected or tended to increase following topical steroid therapy. Topical corticosteroids inhibited cytokine mRNA expression for IL-4 and resulted in a reduction in local Th2 cytokine protein levels.⁵⁴ [****] Corticosteroids inhibited adhesion molecule expression and RANTES secretion.⁵⁵ Local synthesis of IgE is also inhibited, as illustrated by a marked reduction in ϵ -germline gene transcripts and C ϵ mRNA for the IgE heavy chain.²² [****] These effects of topical corticosteroids on the nasal mucosa during late responses have also been confirmed during natural seasonal grass pollen exposure. For example, topical corticosteroid resulted in a marked reduction in nasal mucosal eosinophils and a parallel

reduction in IL-5 mRNA-expressing cells, principally T lymphocytes, within the nasal mucosa (**Figure 12.6**).⁵⁴ [****] Similarly, local upregulation of IL-4 and local IgE synthesis in the nasal during the pollen season was inhibited by topical corticosteroids.⁵⁶ [****] A characteristic feature of seasonal allergic rhinitis is the transepithelial migration of CD1a positive Langerhans cells. Following topical corticosteroids, nasal mucosal Langerhans cells were reduced in the submucosa and absent from the nasal epithelium.⁵⁷ [****]

In summary, topical corticosteroids are highly effective and have profound effects on cell recruitment and activation in allergic rhinitis. It seems likely that these effects are largely mediated either directly on Th2 cells, by downregulating their recruitment, activation and cytokine synthesis, or indirectly via suppression of antigen presenting cells, such as nasal mucosal Langerhans cells (**Figure 12.7**).

Allergen injection immunotherapy

Immunotherapy involves the step-wise incremental injection of increasing subcutaneous doses of allergen, in order to suppress symptoms on subsequent re-exposure to that allergen. Immunotherapy is highly effective in selected patients with a limited spectrum of IgE-dependent allergies.⁵⁸ [****] Immunotherapy is particularly effective in seasonal pollinosis, although less effective in polysensitized patients with perennial disease. Risks are increased in patients with bronchial asthma, in whom immunotherapy is not currently recommended within the UK. In contrast to topical corticosteroids, immunotherapy, when given monthly for three to four years, has been shown to induce long-term remission for at least three years following discontinuation of treatment.⁵⁹ [****] In children, immunotherapy has been shown to reduce the risk of physician-diagnosed asthma at three to five years after commencing treatment⁶⁰ [****] and to prevent the onset of new allergen sensitivities in children.⁶¹ [****] These studies strongly suggest that immunotherapy is the only treatment that has the potential to modify the course of allergic disease.

Immunotherapy has been associated with a decrease in the mucosal recruitment and activation of inflammatory cells, a reduction in the release of inflammatory mediators in target organs and increases in 'protective' serum IgG antibodies.⁶² Immunotherapy suppresses both early and late nasal responses after allergen challenge. Suppression of late responses in the skin and nose has been associated with immune deviation with a reduction in the local expression of Th2 cytokines and an increase in the Th1 cytokine \cdot INF- γ . Recently, pollen immunotherapy was shown to reduce nasal mucosal eosinophil and basophil numbers during the pollen season.⁶³ There were also seasonal increases in the ratio of local INF- γ to IL-5-producing cells in the nasal mucosa after immunotherapy,

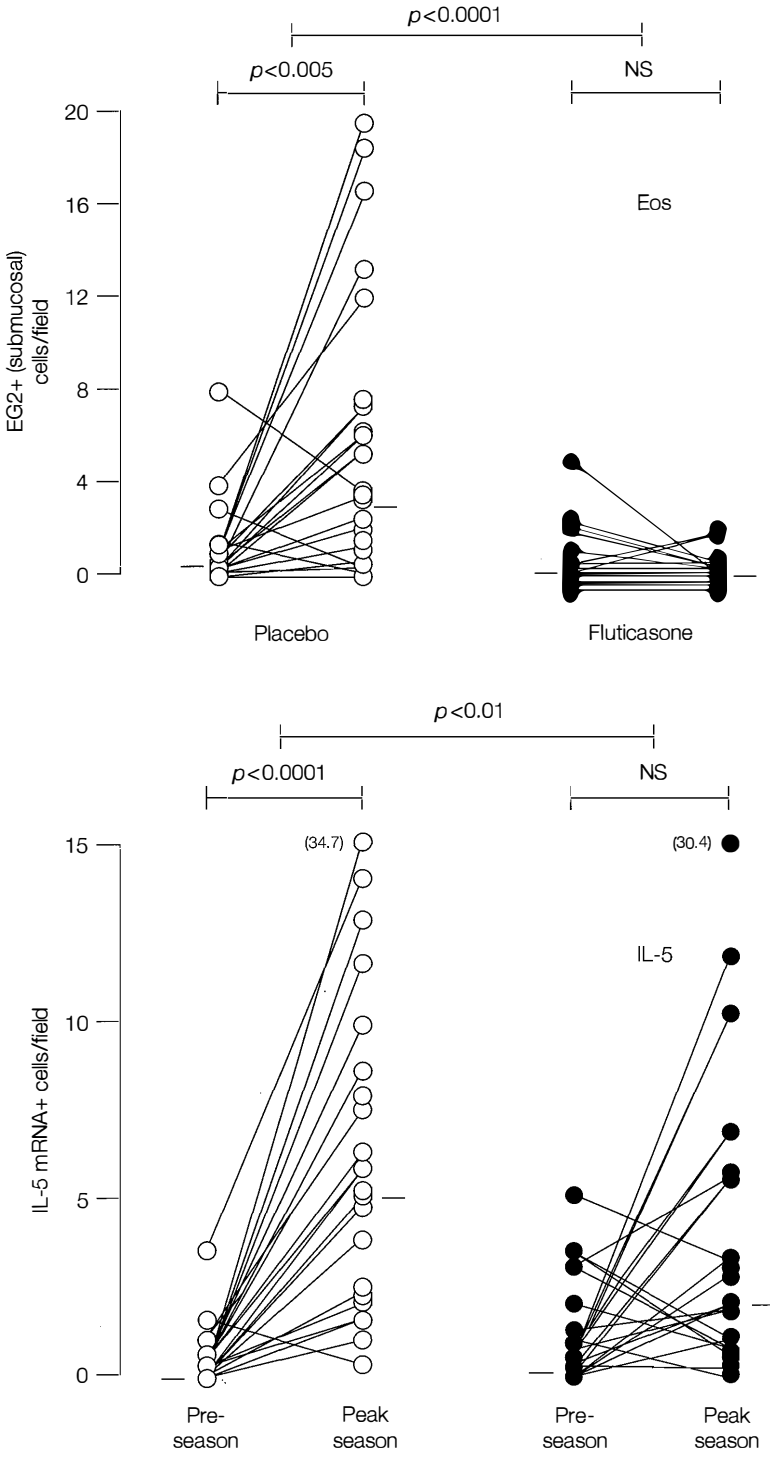

Figure 12.6 Influence of corticosteroids on allergen-induced Th2 responses (nasal mucosal eosinophils and IL-5 expression) during natural seasonal exposure to grass pollen. Reproduced with permission from Ref. 53.

consistent with immune deviation of local T cell responses in favour of Th1 responses (**Figure 12.8**).⁶⁴ In the same nasal biopsies, we identified increases in the number of IL-10 and TGF- β producing cells, detectable at both messenger RNA and protein levels.⁶⁵ Co-localization confirmed that 15–20 percent of these IL-10 and TGF- β producing cells were T cells, results consistent with an immunotherapy induced local mucosal T-regulatory response during natural seasonal exposure. These local increases in IL-10 (and INF- γ) were accompanied by

30–100 fold increases in serum allergen-specific IgG and IgG4 antibody concentrations (**Figure 12.9**). [****] Whereas crude serum IgG antibody levels, in general, have failed to correlate with clinical improvement following immunotherapy, we detected a serum ‘blocking’ activity present within the IgG4 fraction of serum capable of inhibiting IgE-facilitated allergen presentation to T cells.⁴⁰ We have developed a simple flow cytometry assay that measures the binding of allergen-IgE complexes to B cells and its inhibition by the IgG4 fraction contained

Figure 12.7 The mechanisms of steroid suppression of the late phase allergic response.

Figure 12.8 Influence of allergen injection immunotherapy on allergen induced Th2 allergic responses. Immunotherapy induces immune deviation in favour of Th1 responses, as well as Th2 T-cell unresponsiveness, under the influence of the inhibitory cytokines IL-10 and TGF-β, derived, at least in part, from CD4⁺ CD25⁺ T cells. These events result in the emergence of 'protective' IgG, particularly IgG4, antibody responses and downregulation of IgE and tissue eosinophilia.

within post-immunotherapy serum. It seems likely that IgE-facilitated allergen presentation may represent a rate-limiting step in allergen-driven Th2 T-cell responses. Whether or not detection of this 'functional' IgG blocking activity is surrogate and/or predictive of the clinical response to immunotherapy remains to be determined.

In summary, both topical nasal corticosteroids and allergen immunotherapy are highly effective treatments for allergic rhinitis. In contrast to topical steroids, allergen immunotherapy has the potential to induce long-term disease remission. Whereas topical steroids act by downregulation of Th2 T-lymphocyte function (**Figure 12.7**), immunotherapy appears to act either by immune deviation of Th2 in favour of Th1 responses and/or induction of a population of IL-10 producing T-regulatory cells (**Figure 12.8**) which may down-regulate Th2 responses directly or via induction of IgG blocking activity which inhibits IgE-facilitated allergen presentation.

IMPLICATIONS FOR THERAPY

New knowledge concerning the mechanisms of allergic rhinitis and the influence of treatment has identified a number of novel, more targeted strategies (**Figure 12.10**). Obvious candidates are the Th2 cytokines IL-4 and IL-5. IL-4 induces B cell switching, upregulates IgE receptors on mast cells, increases VCAM-1 expression on vascular endothelium, induces mucus secretion and promotes Th2 T-lymphocyte polarization. One study examined the effects of inhaled soluble IL-4-receptor during withdrawal of inhaled corticosteroids in patients with moderately severe atopic asthma. In this small pilot study of two weeks treatment, soluble IL-4 receptor 1500 µg was effective in preventing relapse, as reflected by increases in asthma symptom scores, increase in beta agonist use, and a reduction in FEV₁ in patients on placebo therapy.⁶⁶ Further trials are needed.

Interleukin-5 is a major factor responsible for terminal differentiation of eosinophils from bone marrow

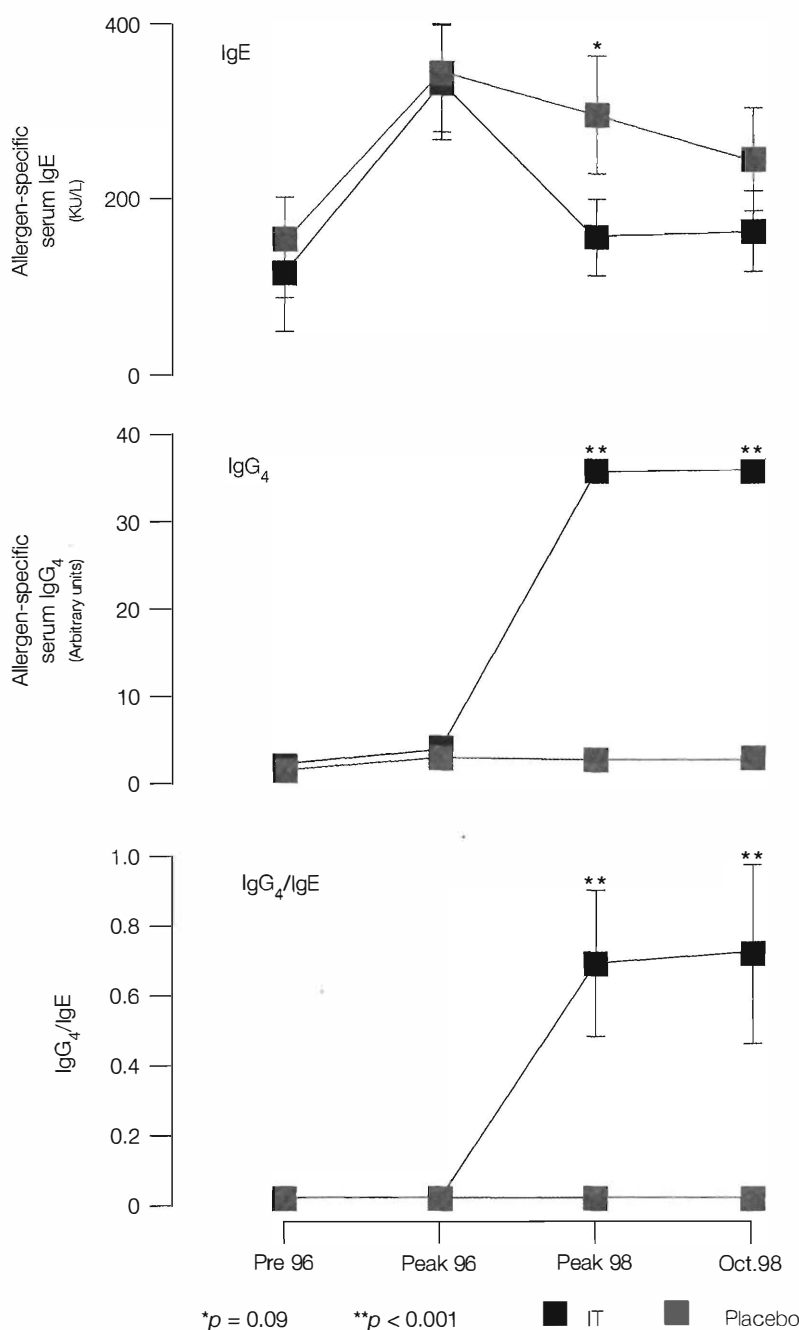

Figure 12.9 Changes in allergen specific IgE, IgG₄ and IgE/IgG₄ ratio (mean \pm standard error) during two years allergen injection immunotherapy. Data shown are for baseline, peak season before treatment, and peak season and out of season following two years immunotherapy. *P*-values refer to comparisons between immunotherapy and placebo groups (Mann-Whitney *U* test).

precursors. Inhaled IL-5 induces airway hyperresponsiveness and sputum eosinophilia. In patients with atopic asthma, an anti-IL-5 blocking monoclonal antibody was effective in reducing allergen-induced blood eosinophilia, whereas no detectable effect on allergen-induced late asthmatic responses or the associated increases in airway hyperresponsiveness was observed.⁶⁷ Recently, anti-IL-5 has been shown to reduce deposition of extracellular matrix proteins in the bronchial subepithelial basement membrane zone in patients with mild asthma,⁶⁸ raising the possibility that long-term anti-IL-5 monoclonal antibody therapy may have a role in preventing airway remodelling in asthma. Recombinant IL-12 in atopic asthmatics, like anti-IL-5 therapy, was effective in

reducing blood eosinophils during four weeks treatment, although had no effect on allergen-induced late asthmatic responses.⁶⁹

In a pilot study in patients with severe bronchial asthma, a more global strategy against T cells was adopted by use of an anti-CD4 monoclonal antibody.⁷⁰ Although there was a modest improvement in peak expiratory flow and symptoms in the high-dose group, further studies have not been performed, presumably in view of concerns of the safety of a general suppression of CD4⁺ helper T-lymphocyte function.

The most successful targeted approach has been with strategies directed against IgE antibody. [****] Subcutaneous anti-IgE antibody given at two to three weekly

Figure 12.10 New knowledge about mechanisms of allergy has resulted in a number of individual more targeted therapeutic strategies. Both anti-IL-5 and IL-12 therapy inhibited eosinophilia but had no effect on allergen-induced late responses. To date, only anti-IgE therapy has proved successful in phase 3 clinical trials of allergic asthma and rhinitis.

intervals has been shown to be moderately effective in seasonal allergic rhinitis.⁷¹ In the first trial of anti-IgE therapy in moderate to severe perennial allergic asthma, a modest reduction in symptoms was noted, and a more convincing reduction in steroid requirements.⁷² In subsequent trials in both adults and children, anti-IgE treatment resulted in clinical improvement, a reduction in corticosteroid use and, importantly, a decrease in the frequency of asthma exacerbations. Anti-IgE therapy is now registered in some countries, although more studies are required to define patients most likely to benefit. A recent study targeted the low-affinity IgE receptor CD23. An anti-CD23 monoclonal antibody (IDEC-152) was well tolerated in man,⁷³ although further studies are required to evaluate clinical activity in allergic asthma.

Of particular current interest are strategies directed against adhesion molecules and chemokine receptors. CCR3 is particularly attractive as a target since it is the dominant receptor expressed by mast cells, eosinophils, basophils and Th2 T-lymphocytes. Also, CCR3 is the common receptor for Eotaxin, RANTES and MCP2, 3 and 4. It is possible that the combination of anti-IL-5 and CCR4 antagonism may more effectively suppress tissue eosinophilia where targeting either alone may be less effective. Alternatively, CCR4 and CCR8 have been identified as putative phenotype-specific receptors for Th2-type T-lymphocytes.³⁰ Increases in CCR4 expression on T-cells in the bronchial mucosa and, more recently, increases in the CCR4-specific ligands macrophage derived chemokine (MDC) and thymus and activation-regulated chemokine (TARC) in bronchoalveolar lavage fluid have been detected during allergen-induced late asthmatic responses. However, to date, no clinical trials of chemokine receptor antagonism in humans have been reported.

Conventional high-dose allergen injection immunotherapy is highly effective in allergic asthma and rhinitis,

although, at present, its use is confined to specialist centres on the grounds of safety. Novel approaches are aimed at retaining or improving efficacy whilst reducing side effects. In general, this involves strategies that increase the immunogenicity (potential to modify T cell responses) whilst reducing the allergenicity (the potential to crosslink IgE on mast cells) of allergen extracts. This may be achieved by the use of alternative routes, the use of adjuvants and the development of modified recombinant major allergens. Sublingual immunotherapy is the most promising alternative route. A recent meta-analysis of 22 randomized controlled trials of sublingual immunotherapy in adults with seasonal and perennial allergic rhinitis confirmed efficacy with minimal side effects.⁷⁴ [****] However, overall, clinical efficacy was modest and further studies are needed to establish the optimal dose and duration of therapy. Alum is a longstanding effective depot adjuvant. Monophosphoryl lipid A (MPL) is a novel derivative of a lipopolysaccharide from salmonella.⁷⁵ MPL may act by inducing IL-12-dependent immune deviation in favour of Th1 responses and has been shown to be effective in seasonal allergic rhinitis. Similarly, the use of short oligonucleotide sequences of bacterial DNA containing an excess of unmethylated CG sequences (immunostimulatory DNA sequences (ISS)) has been explored.⁷⁶ ISS are recognized by Toll-like receptor 9 present on antigen-presenting cells and induce immune deviation of T-lymphocyte responses in favour of Th1 responses. The presence of conjugated ISS sequences also appears to inhibit IgE-crosslinking on mast cells. Preliminary studies in ragweed hay fever have demonstrated modest reductions in seasonal symptoms, accompanied by increases in allergen specific IgG antibody. Another novel approach that has been employed in cat-sensitive patients is the use of small T cell peptide epitopes by intradermal injection.⁷⁷ These peptides are highly immunogenic and repeated

administration in man has demonstrated marked suppression of allergen-induced late cutaneous responses, although further studies are required to assess clinical efficacy.

Alternative approaches involve the combination of conventional immunotherapy with more targeted therapies. For example, the combination of anti-IgE with allergen immunotherapy,⁷⁸ particularly during the updosing phase, is likely to reduce IgE-dependent side effects, whilst allowing administration of optimal doses of allergen to achieve allergen-specific tolerance.

RHINITIS/ASTHMA LINK

The link between rhinitis and asthma has recently been highlighted in a World Health Organization report: Allergic rhinitis and its impact on asthma (ARIA).⁷⁹ Approximately 30 percent of patients with rhinitis develop asthma and up to 80 percent of patients with perennial asthma have rhinitis. The upper and lower airway share the same respiratory pseudostratified respiratory epithelium. Both allergic rhinitis and asthma are characterized by IgE-dependent mast cell activation, tissue eosinophilia and upregulation of Th2-type cytokines.⁸⁰ Both diseases are characterized by epithelial migration of mast cells, eosinophils and basophils and the presence of Langerhans cells within the respiratory epithelium. Both diseases are corticosteroid responsive. Anticholinergics are effective in suppressing mucus rhinorrhoea and bronchospasm and anti-leukotriene drugs have been shown to be at least partially effective in both upper and lower airway allergic disease. [****]

Despite these similarities, important differences between rhinitis and asthma also exist. Whereas in the nose, there are prominent erectile venous sinusoids, there are no venous sinusoids in the bronchial mucosa. Submucosal glands are far more prominent in the upper airway compared to the bronchial mucosa. Airway smooth muscle is a prominent feature in the bronchi and increased in asthma, whereas no airway smooth muscle exists in the upper airway. A prominent feature of even mild allergic asthma is disruption of the bronchial epithelium, whereas in rhinitis, even in longstanding persistent rhinitis, the epithelium remains intact. In asthma, there is a thickening of the sub-basement membrane zone with an increase in collagen deposition, whereas in rhinitis, the basement membrane zone appears normal. Therapeutic differences include the selective effectiveness of β_2 -agonists in asthma and antihistamines in rhinitis. It seems likely that, in general, allergic rhinitis and asthma share a common Th2-driven pathogenesis and that the above differences may largely be explained by the presence of different effector organs (smooth muscle in the lower airway, mucus glands in the upper airway). However, chronic perennial asthma is a more heterogeneous, less Th2-polarized disease and

the relative lack of evidence for airway remodelling in rhinitis compared to asthma remains unexplained.

Although rhinitis and asthma frequently co-exist, it is not clear whether this simply reflects a common mucosal susceptibility to disease in the upper and lower airway or alternatively whether there exists a causal link. Early studies suggested that topical intranasal corticosteroid treatment may improve bronchial asthma symptoms and reduce bronchial hyperresponsiveness. However, these studies were small scale and may possibly reflect a 'positive publication' bias. A recent study examined symptoms and inflammatory changes in the upper and lower airway following nasal allergen provocation.⁸¹ Biopsies from the nasal and bronchial mucosa were taken before and at 24 hours after nasal provocation. Patients developed both nasal and bronchial symptoms and changes in both nasal peak inspiratory and bronchial peak expiratory flow rates. Immunocytochemistry revealed marked increases in the local expression of the adhesion molecules ICAM-1 and VCAM-1, that correlated with eosinophil numbers in both the nasal and bronchial mucosa. Whether there exists a true causal link between allergic rhinitis could be resolved by a large definitive trial comparing the effects of topical nasal versus inhaled corticosteroid treatment on symptoms and inflammatory markers in both the upper and lower airways. As emphasized in ARIA,⁷⁹ whether or not the link is causal, it is clearly important to recognize and treat asthma in patients presenting with allergic rhinitis. All patients should be asked whether they have chest symptoms, including cough, chest tightness, wheeze and shortness of breath. Asthma symptoms tend to be episodic, worse at night and respond to inhaled bronchodilators. Particular triggers include exercise, viral colds and common aeroallergens. A peak expiratory flow (best of three recordings), with reference to predicted normal values, is the minimum requirement for an objective test of airflow limitation in the ENT clinic. Where doubt remains, consideration should be given to the performance of spirometry, reversibility testing in response to an inhaled bronchodilator and the request of serial peak flow measurements at home/in the work place. Alternatively, if such tests are unavailable, early referral to a chest physician would be appropriate.

TESTS

A skin prick test (SPT) provides objective confirmation of IgE sensitivity although must always be interpreted in the light of the clinical history. SPTs (or radioallergosorbent assay tests (RAST)) using a limited number of allergens (grass, house dust mite, cat) may confirm or exclude the diagnosis of atopy. SPTs identify sensitization although cannot predict clinical relevance independent of the history. In general, SPTs are more sensitive, whereas serum allergen-specific IgE measurements may be more

specific. The reliability of SPTs depends upon the competence of the operator, the content of major allergenic determinants in the extract, its shelf-life, and the need for storage of extracts at +4°C.

Skin prick testing requires training in performance and interpretation of results. Antihistamines should be avoided for two to three days before skin testing, whereas oral corticosteroids do not significantly inhibit SPT results. They should be performed on the flexor aspect of the forearm using sterile lancets. The procedure should be painless and not draw blood. An unequivocal positive test is one 3 mm greater than the negative control test with allergen diluent. Skin tests should not be performed in the presence of severe eczema. The presence of dermatographism may confound results. However, dermatographism will be identified by the presence of a positive prick test with the negative control solution, due to the minor trauma of the procedure. For routine clinical use, the skin test result is recorded as the mean diameter of the skin weal, excluding pseudopodia, expressed in millimetres and compared with the negative control (allergen diluent). Examples of skin tests are shown in **Figure 12.11**. The value of SPTs is summarized below:

- diagnosis of atopy;
- supportive evidence (positive or negative) for clinical history;
- essential if avoidance measures are being considered;
- educational value: visual reinforcement of verbal advice.

In hospital practice, a routine panel of SPTs might include house dust mite, animal danders (cat fur, dog hair and horse hair), moulds (*aspergillus*, *cladosporium* and *alternaria*), and pollens (birch, mixed trees, timothy or mixed grasses and weeds), and a positive (histamine 10 mg/mL) and negative (allergen diluent) control. Skin

Figure 12.11 Skin prick tests in allergy diagnosis. The weal size is recorded as mean diameter in millimetres. A positive test is 3 mm greater than the negative control test using allergen

fruit and egg that are unstable, heat-labile allergens. Skin testing may also be useful for certain drug allergies including penicillin, general anaesthetics and neuromuscular blocking drugs in addition to latex allergy. It is debatable whether SPTs should routinely be performed in general practice. A pilot study of patients with newly diagnosed asthma, performed by nurses in the context of primary care, suggested that the procedure raised nurses' awareness of the role of allergy in asthma and rhinitis.⁸² In particular, the study highlighted the value of negative skin prick tests for excluding atopic allergy in these subjects. [***] However, the downside was that, despite training in performance and interpretation, nurses tended to place more reliance on the skin test rather than the clinical history of allergic sensitivities.

Total IgE

Total IgE levels are usually below 200 ng/mL in non-allergic adults. In atopic adults, results may vary from within the normal range up to 600 ng/mL, or higher levels. Cord blood levels are around 1 ng/mL and it is debatable whether cord blood IgE has any prognostic value. Approximately half of IgE-allergic adults will have a total IgE within the normal range, such that the predictive value of total IgE is poor. However, the presence of very high total IgE levels in serum, such as may occur in disorders such as atopic eczema, may give rise to false positive marginally raised allergen-specific IgE tests. It is therefore valuable to know the total IgE level when interpreting the results of borderline allergen-specific IgE tests.

Allergen-specific IgE

Allergen-specific IgE in serum is measured in specialist immunology or clinical chemistry laboratories by radio-immuno assay (RIA), enzyme-linked immunosorbent assays (ELISA) or chemiluminescence methods. The best-known test for allergen-specific IgE is the radio-allergosorbent test (**Figure 12.12**). In this test, allergen extract is covalently bound to a paper disc. A small amount of patient serum is added and any immunoglobulin specific for that particular allergen binds to the allergen. After vigorous washing, radiolabelled anti-IgE is incubated for a defined period. After further washing, the level of radioactivity is counted. In an ELISA, the anti-IgE is linked to an enzyme. When the relevant substrate is added the enzyme yields a coloured product that is measured in a colorimeter. In chemiluminescence assays, anti-IgE is linked to luciferase that emits photons which can be measured. The sensitivity of the tests varies, depending on the quality of the allergen extract used, the need to optimize the detection system and the proficiency

Figure 12.12 Allergen-specific IgE measurements: RAST. The detection system measures binding of radiolabelled anti-IgE. ELISA employs an enzyme label that is detected by addition of enzyme substrate. Enzyme–substrate interaction results in a coloured product that is detected by spectrophotometry.

the RAST test is around 80 percent and specificity is higher than for skin tests, often greater than 90 percent. The test will therefore occasionally ‘miss’ IgE-sensitive patients, but if the RAST is positive, most patients will be IgE-sensitive. RAST tests have the advantage of complete safety, and testing is possible with a wider range of allergens than for skin tests. Also, drugs such as antihistamines or the presence of skin disease do not influence RAST tests.

Basophil histamine release

This test relies on assessing histamine release from blood basophils added to allergen extract. Whole blood is added to an ELISA plate precoated with the relevant allergen. After incubation at 37°C for one hour, histamine release is measured by fluorescence assay or by RIA. This test requires fresh blood and needs to be performed in specialist laboratories, although it only takes a few hours to obtain a result. One disadvantage is that 5 percent of the population have basophils which do not release histamine. For this reason, a positive control such as anti-IgE should be included with all tests, in order to validate a negative test.

Provocation tests

Provocation testing with allergen in target organs is only very rarely used in routine allergy diagnosis. They may be employed in tertiary centres where there is discordance between the results of SPTs and the clinical history. However, there are problems with interpretation since accurate threshold levels for a positive or negative response have not been determined in relation to their clinical relevance. However, in view of new knowledge concerning local IgE synthesis, such tests may be of value,

for example in a patient with a clear cut history of allergic symptoms on exposure to an allergen, but with negative skin test/RAST test results to that allergen.

In contrast, measurement of nonspecific hyperresponsiveness, for example by histamine or methacholine inhalation testing, is helpful in assessing the presence and severity of asthma, particularly in patients with a clear history of bronchial asthma, when baseline lung function is normal and there is no detectable immediate response to a bronchodilator. In such cases, detection of increased methacholine or histamine airway responsiveness indicates the need for a therapeutic trial of a bronchodilator and further monitoring.

Serum tryptase

Tryptase is a serine protease, molecular weight 130,000. There are two distinct forms with 90 percent sequence homology, α -tryptase and β -tryptase, of which only β -tryptase is enzymatically active. β -tryptase predominates in allergic reactions, whereas both α - and β -tryptase are detectable in systemic mastocytosis. An elevated serum tryptase level indicates mast cell activation and mediator release. Tryptase assays may be valuable in the differential diagnosis of anaphylaxis from other problems such as vasovagal syndrome, angio-oedema, and carcinoid syndrome.⁸³ Blood should be taken approximately one hour after the reaction (tryptase levels peak at around 45–60 minutes and then gradually fall over four to six hours). Advantages of the test are that, unlike histamine, blood may be stored, if necessary overnight, and serum separated the following day.

Diagnostic approach

The diagnostic approach to allergy is summarized in **Figure 12.13**. The following questions should be asked:

- Is the patient atopic?
- Does allergy contribute to the patient’s symptoms?
- Which are the clinically relevant allergens?

All patients presenting with asthma, rhinitis, eczema or gastrointestinal symptoms should be questioned about potential allergic causes. Also, whether or not allergy is suspected, in the authors’ view, SPT to house dust mite, cat and grass pollen should be performed in order to confirm or exclude the presence of atopy. Additional tests should only be based on possible relevance determined by the clinical history. In the majority of patients, there will be concordance between the history and skin test or RAST test results. A negative history and negative tests excludes allergy and indicates that no allergy-specific treatment is required. In patients with a positive history confirmed with objective confirmation by skin or RAST testing, allergen specific measures such as allergen avoidance or, in selected

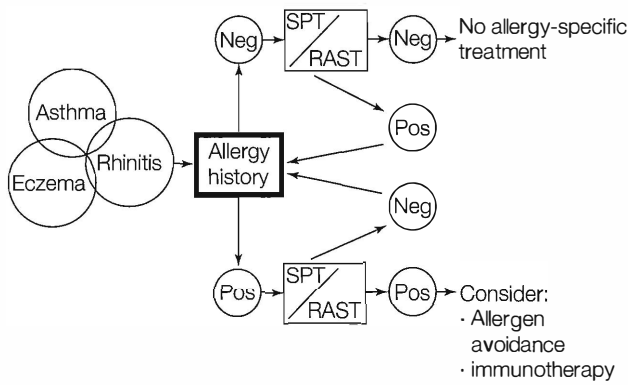

Figure 12.13 An approach to allergy diagnosis.

patients, immunotherapy should be considered. Where there is discordance, then initially, the history should be retaken and, if necessary, tests repeated. If doubt remains, specialist referral for re-evaluation and, if necessary, specific provocation testing can be performed. Ultimately, a therapeutic trial of intervention may be necessary. For example, in patients suspected of IgE-mediated food allergy, a period of dietary exclusion and/or double-blind placebo-controlled food challenge may be indicated. A skilled specialist allergy nurse and the availability of a dietitian with expertise in food allergy are essential for an effective specialist allergy diagnostic service.

KEY POINTS

- Genetic and environmental factors interact as causes of allergic disease.
- Allergic inflammation is characterized by IgE-dependent activation of mast cells and tissue eosinophilia.
- These events are under the regulation of Th2 T lymphocytes.
- Corticosteroids suppress Th2 T lymphocyte responses.
- Immunotherapy induces allergen-specific immune deviation in favour of Th1 responses and/or allergen specific T cell tolerance, probably under the influence of T regulatory cells.
- A number of novel targeted immunotherapeutic approaches have been tested in clinical trials. So far, only anti-IgE has been successful.
- Allergic rhinitis and asthma are commonly associated. Always check for asthma in patients presenting with rhinitis.
- Skin tests and RAST tests indicate IgE sensitivity only and must always be interpreted in the context of the clinical history.

Best clinical practice

- ✓ The diagnosis of allergic disease is based principally upon a careful clinical history. Allergic rhinitis is characterized by nasal itch, sneeze and watery discharge and the seasonal or perennial nature of these symptoms should be noted. Summer hay fever is recognized to cause significant morbidity and the impact of the disease upon the patient's work and leisure activities should be considered.⁸⁴ Chest symptoms, in particular shortness of breath and wheeze, may indicate the presence of associated allergic asthma.
- ✓ The examination of patients with allergic rhinitis is often unremarkable, but the nasal mucosa should be inspected with either a flexible or rigid nasendoscope to rule out other conditions or exacerbating factors, in particular septal deflection, nasal polyps or chronic rhinosinusitis.
- ✓ Atopic individuals produce allergen-specific IgE to one or more of the common aeroallergens and may be quickly and reliably identified by skin prick testing in the clinic. In hospital practice, a routine panel of skin prick tests includes house dust mite, animal danders (cat fur, dog hair and horse hair), moulds (*Aspergillus*, *Cladosporium* and *Alternaria*) and pollens (birch, mixed trees, Timothy or mixed grasses, and weeds), and positive (histamine 10 mg/mL) and negative (allergen diluent) controls. Responses are recorded as the weal diameter, excluding pseudopodia, at 15 minutes. A positive prick test is defined as a weal diameter 3 mm or greater than that of the negative control test. The results should only be interpreted in conjunction with the clinical history and tests should not be performed when the patient is taking antihistamines as these will reduce the clinical response.
- ✓ In the presence of dermatographism or eczema, serum IgE antibodies to specific antigen may be measured by RAST. In general, skin prick tests are a more sensitive test of atopy, whereas serum allergen specific IgE measurements are available for a wider panel of allergens than skin test reagents. A raised total IgE level is usually found in atopic individuals, but may also be found in other conditions such as helminth disease.
- ✓ Pharmacotherapy is the mainstay of treatment for allergic rhinitis and most medications are designed to target inflammatory mediators.
- ✓ Antihistamines are H1 receptor antagonists that have been used as first-line treatment for seasonal allergic rhinitis for many years.^{85, 86} They are effective at relieving the early symptoms of hay fever in particular sneeze, itch and nasal discharge, but considered less effective at reducing nasal congestion.⁸⁷ The first generation antihistamines

(Chlorpheniramine, Bropheniramine) were recognized to cause drowsiness in a proportion of patients and indeed have been associated with impaired performance at home and at work.⁸⁸ The second generation antihistamines such as Loratidine, Fexofenadine and Desloratadine are non-sedating.

- ✓ Intranasal corticosteroids are considered first-line treatment for more severe symptoms of allergic rhinitis and are highly effective in suppressing all symptoms of allergic rhinitis, including nasal obstruction. Preparations include Beclometasone, Budesonide, Fluticasone, Triamcinolone and Mometasone. Topical corticosteroids are effective at improving nasal airflow,⁸⁹ in addition to relieving the symptoms of itch, sneeze and nasal discharge.⁹⁰ Traditionally, topical corticosteroids have been administered on a regular basis, but more recently as needed use of Fluticasone propionate has been found to be effective in the treatment of seasonal allergic rhinitis.⁹¹
- ✓ Weiner *et al.*⁹² reported in a meta-analysis of 16 randomized controlled trials that intranasal steroids were more effective than oral antihistamines at relieving the symptoms of allergic rhinitis. Others have reported that both medications may be required to provide optimum treatment in more severe cases.⁹³
- ✓ However, in a large postal survey in the UK, of those patients who were regularly using a non-sedating antihistamine and nasal steroid spray, 62 percent still experienced troublesome residual symptoms and described symptom control as partial or poor.⁹⁴
- ✓ In a small proportion of patients whose symptoms are not otherwise controlled, a short course of prednisolone (20 mg daily for five days) may be prescribed and is highly effective at relieving all nasal symptoms, including nasal obstruction in the majority of patients.⁹⁵
- ✓ Sodium cromoglycate is a membrane stabilizer that inhibits mast cell degranulation and the release of mediators. It reduces nasal discharge and congestion, but is less effective than topical corticosteroids and must be administered to the nasal mucosa four times daily.⁹⁰ Topical Cromoglycate eye drops are useful for allergic eye symptoms in many, but must also be administered three to four times daily. Intranasal anticholinergics relieve rhinorrhoea but do not greatly improve the other symptoms of allergic rhinitis.
- ✓ Leukotriene receptor antagonists, such as Montelukast, have been shown to have anti-inflammatory properties and to have beneficial effects on asthma disease control.⁹⁶ However, a metaanalysis of 11 studies involving over 4000 patients reported that leukotriene receptor antagonists are minimally better than placebo, but less effective than nasal

corticosteroids at improving symptoms and quality of life in patients with seasonal allergic rhinitis.⁹⁷

- ✓ Allergen avoidance is possible for some allergens, such as latex and certain foods, but is less effective for hay fever owing to the ubiquitous nature of pollen. Avoidance of wide open and grassy spaces may be helpful, particularly in the late afternoon and evening when pollen counts are highest. Cars may be fitted with pollen filters and windows in cars and buildings may be kept tight shut.
- ✓ Measures to reduce house dust mite exposure are often recommended and include the removal of soft furnishings, such as carpets and curtains, and the provision of mite proof covers for the pillows, duvets and mattresses. However, trials to date have been small and of poor methodological quality. This has made it difficult to offer any definitive recommendations on the role, if any, of house dust mite avoidance measures in the management of house dust mite-sensitive perennial allergic rhinitis.⁹⁸ Allergen-impermeable covers, as a single intervention for the avoidance of exposure to dust-mite allergen, are clinically ineffective in adults with asthma.⁹⁹
- ✓ Allergen-specific immunotherapy is an effective intervention that involves the incremental administration of subcutaneous allergen extract for 8–16 weeks followed by monthly injections for up to three to five years. It is the only currently available intervention that can modify the disease process and long-lasting benefit has been reported.⁵⁹ A recent review of 51 randomized, placebo-controlled clinical trials confirmed that specific allergen injection immunotherapy in suitably selected patients with seasonal allergic rhinitis results in a significant reduction in symptom scores and medication use.¹⁰⁰
- ✓ The treatment, however, requires injections for a number of years and carries the risk of local skin reactions and rare, but potentially fatal, anaphylaxis. The risks of systemic reactions are significantly increased in those patients with concomitant asthma. Efficacy is limited in those with multiple sensitivities. In the UK allergen-specific immunotherapy is restricted to tertiary referral centres thereby limiting patient access to this form of treatment.
- ✓ More recently sublingual immunotherapy has become available as a mainstream treatment for seasonal allergic rhinitis. A review and metaanalysis of 22 trials involving 979 patients concluded that overall there was a significant reduction in both symptoms (SMD-0.42, 95 percent confidence interval - 0.69 to - 0.15; $p = 0.002$) and medication requirements (SMD-0.43 (- 0.63, - 0.23); $p = 0.00003$) following immunotherapy.¹⁰¹

Evaluation of the immune system

ELIZABETH DREWE AND RICHARD J POWELL

Introduction to evaluation of the immune system	167	Deficiencies in current knowledge and areas for future research	172
Immunological tests	167	References	173
Key points	172		
Best clinical practice	172		

SEARCH STRATEGY AND EVIDENCE-BASE

The information in this chapter is taken from standard UK immunology laboratory practice. It reflects expert opinion (level 4 evidence) with regards to immunology tests currently performed in the UK.

INTRODUCTION TO EVALUATION OF THE IMMUNE SYSTEM

Evaluation of the immune system broadly encompasses the investigation of immunodeficiency, autoimmune disease including vasculitis, allergy and lymphoproliferative disease. Diagnosis results from studying the combination of clinical presentation and investigations including immunological, haematological, microbiological and histopathological, with increasing recognition of the place of genetic and molecular biological approaches. However, tests in isolation are rarely diagnostic. Some understanding of the sensitivity (proportion of true positives correctly identified), specificity (proportion of true negatives correctly identified) and the positive predictive value (likelihood an individual has a disease given a positive result) for each test is required.

Interpretation of results reflects the age and sex of the patient. This is particularly evident for the investigation of childhood immunodeficiency when a lymphocyte count that would be normal for an adult, may signify an underlying immunodeficiency in an infant. Similarly, a low positive anti-nuclear antibody (ANA) titre may be a normal finding in a middle-aged female, but be highly suggestive of an autoimmune process in female teenagers or in males of any age.

The investigations will ultimately depend on the clinical presentation and may be guided through discussion with a clinical immunologist. Whilst rare immunological diseases will only be recognized by the appropriate investigation, consideration must also be given to commoner diseases with a similar presentation, for example, cystic fibrosis.

IMMUNOLOGICAL TESTS

Immunodeficiency

Investigation for immunodeficiency should be targeted at patients with persistent or recurrent infections not responding to antibiotics, or patients with unusual or opportunistic infections.¹ Recurrent sinopulmonary infections are a common presentation of primary immunodeficiency and ENT workers should look out for these individuals and initiate the appropriate investigations. It is estimated that half of the patients with primary antibody deficiency in the UK remain undiagnosed.² Remember that early diagnosis of primary immunodeficiency does lead to an improved outcome, emphasizing the need to consider this diagnosis.

Table 13.1 Outline of associations between pathogens and specific immunodeficiencies.

Pathology	Immunodeficiency
Bacterial infections	Antibody deficiency T cell deficiency Complement Neutrophil disorders
Viral infections	T cells Antibody deficiency
Fungal infections	Neutrophil disorders T cells
Neisserial infections	Complement
Abscess formation	Neutrophil disorders.
Mycobacterial infection	T cells Macrophage/cytokines

Table 13.2 Outline of immunological tests for primary immunodeficiency.

Deficiency	Tests
T lymphocytes	Number Surface marker analysis Lymphocyte proliferation studies
Antibody deficiency	Total immunoglobulins Vaccine specific immunoglobulins IgG subclasses B cell number
Phagocyte disorders	Neutrophil number NBT test Phagocytosis and killing studies
Complement disorders	Functional complement assays Assay individual complement components

When considering immunodeficiency, the type of pathogen may provide a clue to the underlying disease and appropriate tests required (Tables 13.1 and 13.2). Certain tests require laboratory preparation, hence require prior arrangements.

C-REACTIVE PROTEIN

C-reactive protein (CRP) levels reflect the acute phase response and are particularly elevated in bacterial infections, malignancy and active vasculitis. An elevated CRP may be helpful in diagnosing intercurrent infection in immunodeficiency and in individuals on high dose steroids.

IMMUNOGLOBULINS

Serum levels of immunoglobulin classes IgG, IgA and IgM are a first line test for investigation of immunodeficiency.

IgG and IgA levels are typically low in common variable immunodeficiency, although a raised IgM with low IgG and IgA is characteristic of hyper IgM syndrome. An elevated IgG is often seen in chronic granulomatous disease. Other indications for immunoglobulin testing include infective and inflammatory diseases and the evaluation of lymphoproliferative disease.

IMMUNOGLOBULIN SUBCLASSES

Testing of IgG subclasses may be an adjunct to the diagnosis of immunodeficiency. Isolated low IgG2 levels may be normal in childhood, but may amount to significant immunodeficiency in combination with IgA deficiency or failure to respond to pathogens, e.g. pneumococcus. Specific vaccine responses appear more informative in the evaluation of humoral immunodeficiency than IgG subclass quantification.

SPECIFIC ANTIBODIES

Assessing if a patient has produced IgG antibodies to a previously encountered pathogen or vaccination plays an important part in diagnosing antibody deficiency, especially in patients who have borderline or normal immunoglobulin levels. Additional immunization, for example tetanus, pneumococcus and haemophilus b, may be given followed by repeat measurements of specific antibody levels after four to six weeks. Failure to mount an adequate response is a pointer to an underlying immunodeficiency. Live vaccines must not be given to patients with a suspected immunodeficiency.

LYMPHOCYTE PHENOTYPING

A reduced lymphocyte count may require evaluation of lymphocyte subsets. Lymphocyte phenotyping by flow cytometry allows accurate quantitative measurements of cell subsets by detection of cell surface markers. The two main T cell subsets are evaluated by assessing CD3⁺ CD4⁺ and CD3⁺ CD8⁺ numbers whilst CD19⁺ cells identify B cells. Low T and/or B cells may occur with severe combined immunodeficiency whereas absence of B cells is a feature of X-linked agammaglobulinaemia. However, these findings are not diagnostic and may be affected by drugs or an intercurrent infection. Low CD3⁺ CD4⁺ cell numbers are characteristic of human immunodeficiency virus (HIV) infection. However, a normal CD4 count does not exclude HIV nor should it be used as a covert screening test. Phenotypic markers can be valuable in the diagnosis of lymphoproliferative disease.

LYMPHOCYTE PROLIFERATION

This specialized test is reserved for the investigation of suspected cellular immunodeficiency following liaison with

an immunologist. The proliferation of lymphocytes can be measured following *in vitro* stimulation by mitogens such as phytohaemagglutinin, or antigens such as tetanus, to which the patient has previously been exposed.

COMPLEMENT PATHWAY LEVELS (C3, C4, C1 INHIBITOR)

Specific components of the complement pathway can be measured, and C3 and C4 levels in particular. Raised levels may suggest an acute phase response where low levels may occur with inflammatory diseases and rare hereditary immunodeficiencies. A low C4 may also occur with C1 inhibitor deficiency (hereditary angioedema (HAE)) and a normal level during an attack excludes this diagnosis. C1 inhibitor levels can also be measured, with functional tests being reserved for those few individuals with a high clinical index of suspicion when normal C1 inhibitor levels are found. Defects in functional assays of complement activity (discussed below) may suggest a rare hereditary complement deficiency that requires individual components of the complement pathway to be assayed at a specialist laboratory.

COMPLEMENT ACTIVITY (CH50 AND AP50)

These tests are reserved for atypical cases of lupus (classical pathway deficiencies), recurrent bacterial infections (alternative pathway defects) and recurrent neisserial infections (terminal pathway deficiencies). Low activity during a period of health suggests an underlying hereditary defect requiring identification.

NITRO BLUE TETRAZOLIUM TEST

The traditional test for the diagnosis of chronic granulomatous disease (CGD) is the nitro blue tetrazolium (NBT) test, where the absence of a neutrophil oxidative burst results in patients' leukocytes failing to reduce NBT dye to a blue precipitate during phagocytosis. Carriers may also be detected by this method.

PHAGOCYTOSIS AND KILLING

This test is technically difficult but remains helpful for the evaluation of neutrophil disorders. Patients' cells are mixed *in vitro* with bacteria or fungi. The presence of viable microorganisms outside the cells is compatible with phagocytic defects whereas intracellular killing defects, for example CGD, are characterized by a reduction in killed intracellular microorganisms.

MOLECULAR AND GENETIC STUDIES

Over the last decade, the molecular defects underlying many primary immunodeficiencies have been recognized, allowing confirmation of disease by detection of genetic

mutations. Examples include some forms of severe combined immunodeficiency, X-linked agammaglobulinaemia, X-linked hyper-IgM syndrome, CGD and X-linked lymphoproliferative disease.

Allergy

A brief discussion of allergy tests follows, although this subject will be discussed further in Chapter 12, Allergy: basic mechanisms and tests. When diagnosing allergy, a clear and detailed history is paramount. Detection of allergen specific IgE can be used to test for a wide range of inhaled and food allergens.³ This can be performed *in vivo* by skin prick tests or *in vitro* on serum using the outdated term radioallergosorbent assay test (RAST). Modern enzyme-linked immunosorbent assay (ELISA) tests have replaced RASTs. The presence of specific IgE *in vivo* or *in vitro* does not necessarily indicate clinical allergy, emphasizing the importance of the patient's history. Results in both circumstances are also dependent on the sensitivity or specificity of the allergen in the solution or assay.

SKIN PRICK TESTS

Drops of aqueous solutions of relevant allergens, negative (allergen buffer) and positive controls (histamine) are applied to the skin. A pinprick is made through the drop placed on the epidermis and excess solution removed with tissue. The size of any localized skin reaction is measured at 15 minutes, and results > 2–3 mm diameter larger than the negative control are considered positive. Antihistamines should be stopped several days before testing, to prevent false negative results.

IgE

IgE levels may be raised in allergic diseases, particularly eczema, and also with certain parasitic infections, immunodeficiencies and lymphomas. A total serum IgE is useful when interpreting *in vitro* allergen specific IgE levels as patients with very high serum IgE levels may give false positive results.

SPECIFIC IgE

Measuring serum IgE antibodies specific to relevant antigens is an *in vitro* method for diagnosing allergy. It is especially useful if patients have widespread skin disease which would make skin prick testing difficult. However, this test has poor specificity when compared with the skin prick test.

ANAESTHETIC REACTION TESTING

Hypersensitivity reactions occurring during surgery may be difficult to differentiate from other simultaneous

Table 13.3 Interpretation of autoantibodies in typical autoimmune screen.

Autoantibodies	Disease	Further tests
Thyroid microsomal	Autoimmune hypo and hyperthyroidism	Thyroid function tests
Gastric parietal cell	Pernicious anaemia	B12 levels Intrinsic factor antibodies
Mitochondrial	Primary biliary cirrhosis	Immunoglobulins Liver function tests
Smooth muscle	Autoimmune liver disease Viral infections, e.g. EBV	Liver function tests
Anti-nuclear antibodies	Connective tissue disease, e.g. lupus	dsDNA, ENA antibodies Complement levels BP and urinalysis

haemodynamic events. Serial evaluation of serum tryptase may be helpful in this situation. A clear history detailing all drugs and fluids given and possible peri-operative sources of latex exposure is essential if the precipitating cause is to be identified. Subsequent skin testing to general anaesthetic agents and latex, may be appropriate in some cases.

Autoimmune disease including vasculitis

The presence of serum autoantibodies is a helpful aid in the management of a variety of autoimmune diseases and vasculitis and should be considered in the light of the clinical history and the outcome of appropriate tissue biopsies.⁴ Some autoantibodies are considered to contribute to disease pathogenesis whilst others are secondary to tissue damage but are nevertheless useful disease markers. High levels of IgG class autoantibodies, are more likely to reflect autoimmunity and disease compared to those of the IgM class. The major use of autoantibody testing is for diagnosing disease. Certain tests are helpful for monitoring disease, for example anti-glomerular basement membrane antibodies, whilst some provide information on disease prognosis, for example cytoplasmic anti-neutrophil cytoplasmic antibodies (ANCA) and anti-proteinase-3 antibodies in Wegener’s granulomatosis. In some circumstances, for example thyroid disease, autoantibodies may predate clinical disease identifying patients who require observation. False positive autoantibodies may occur with a range of infections, drugs and malignancy and some may also occur in healthy individuals. The most frequently performed autoantibody tests will be discussed, other tests not mentioned may require liaison with the immunologist.

AUTOIMMUNE SCREEN

An autoimmune screen evaluates autoantibodies associated with some of the commoner autoimmune diseases.

There is, however, some variation between laboratories in which autoantibodies are evaluated. Autoimmune thyroid and liver disease, pernicious anaemia and lupus are typically sought. The corresponding autoantibodies are outlined in **Table 13.3**.

RHEUMATOID FACTOR AND RHEUMATOID ARTHRITIS

A positive rheumatoid factor (an autoantibody against IgG) occurs in approximately 75 percent of cases of rheumatoid arthritis although its absence does not exclude this diagnosis. It also occurs in Sjogren’s disease, SLE, cryoglobulinaemia and certain infections.

dsDNA ANTIBODIES AND LUPUS

The presence of high titre IgG anti-dsDNA (double stranded DNA) antibodies in a patient with positive ANA antibodies is highly suggestive of lupus. However, only 50 percent of patients with lupus will have positive dsDNA antibodies at some time in their illness; some of the remainder have positive extra nuclear antigen (ENA) antibodies, as described below.

ENA ANTIBODIES AND CONNECTIVE TISSUE DISEASE

The detection of positive ENA autoantibodies in a patient with a positive ANA is suggestive of connective tissue disease and may help categorize the illness. For example, Ro, and sometimes La, antibodies occur with Sjogren’s disease, Sm antibodies are associated with lupus and are predictive of increased risk of renal lupus and anti-ribonucleoprotein (RNP) antibodies occur with lupus and its overlap syndromes.

CENTROMERE, SCL-70 ANTIBODIES AND SCLERODERMA

Scleroderma (progressive systemic sclerosis) is a connective tissue disease characterized by skin sclerosis and

internal organ fibrosis involving lungs, oesophagus and kidney. It can present with dysphagia, and the presence of telangiectasia or a history of Raynaud’s phenomenon are clues to the diagnosis. A positive ANA with Scl-70 antibodies occurs in widespread disease whereas anti-centromere antibodies are typically associated with calcinosis, Raynauds, esophageal dysmotility, sclerodactyl and telangiectasia (CREST) syndrome.

ANCA AND VASCULITIS

The diagnosis of vasculitis, wherever possible, relies on tissue biopsy. However, autoantibody evaluation has a role in reaching a definitive diagnosis, identifying patients who need urgent assessment and, in some cases, monitoring disease. Great care is needed in interpreting these autoantibodies. Infective endocarditis and HIV infection clinically mimic vasculitis and may give rise to false positive test results. A positive c-ANCA is typically associated with Wegener’s granulomatosis whereas a p-ANCA (perinuclear ANCA) is compatible with microscopic polyangiitis (MPA) or Churg–Strauss syndrome. The presence of anti-proteinase-3 (PR3) and anti-myeloperoxidase (MPO) antibodies respectively, add specificity to these diagnoses. A negative ANCA will occur in 15–20 percent of patients with these vasculitides (Table 13.4).

CARDIOLIPIN ANTIBODIES AND ANTIPHOSPHOLIPID SYNDROME

The anti-phospholipid syndrome has great clinical diversity and features include recurrent venous and arterial thrombosis, recurrent pregnancy loss and thrombocytopaenia, and neurological disease due to both small and large vessel occlusion. Presentation to an ENT surgeon might include vertigo or a nasal perforation. Anti-cardiolipin antibodies (and also anti β -2 glycoprotein 1 antibodies) may suggest a diagnosis of anti-phospholipid (APL) syndrome. Anti-cardiolipin antibodies may also occur in association with connective

tissue diseases, for example lupus, but also occur with infections (including HIV), lymphoproliferative disease and drugs, for example anti-epileptics and anti-psychotics. Repeat testing may be indicated to exclude transient autoantibody production secondary to infection. The lupus anti-coagulant assay (usually performed in haematology) is a functional test assessing blood coagulation, and should be performed concurrently.

CRYOGLOBULINAEMIA

Cryoglobulins are immunoglobulins that form gels or precipitates on cooling. Clinical features include purpura, Raynauds syndrome, thrombosis, neuropathy and vasculitis. They are associated with infections, connective tissue disease and lymphoproliferative disease. Detection relies on the appropriate collection into a prewarmed blood tube in a waterbath/vacuum flask. Cold agglutinins are autoantibodies that reversibly agglutinate erythrocytes in the cold and should not be confused with cryoglobulins.

COELIAC DISEASE

Coeliac disease is characterized by malabsorbtion and weight loss but can present with oral ulceration, anaemia and malaise. The presence of villous atrophy on duodenal biopsy remains the gold standard for diagnosis but serological tests are an invaluable screen. IgA endomysial antibodies occur in over 95 percent of Coeliac disease patients although they may be negative in individuals with IgA deficiency or in patients established on a gluten free diet. IgA anti-transglutaminase antibodies are emerging as an alternative test. Anti-gliadin antibodies may be helpful for diagnosing Coeliac disease in children and IgA deficiency but they are less specific, occurring with gastrointestinal infection and inflammation.

BULLOUS PEMPFIGOID AND PEMPFIGUS

Bullous pemphigoid is associated with autoantibodies to the dermo-epidermal junction or mucosal basement membrane zone leading to cutaneous and mucosal blisters, particularly in the elderly. Circulating autoantibodies are positive in approximately 75 percent of cases. Direct immunofluorescence examination of perilesional biopsy material, however, reveals linear deposits of C3 and IgG at the basement membrane in nearly all cases. Pemphigus is a blistering disease associated with serum intercellular autoantibodies in nearly all cases. These antibodies, usually at low titre, may also occur with burns and infections. Direct immunofluorescence examination is helpful for the diagnosis of pemphigus revealing linear intraepithelial IgG. The intraepithelial pathology in pemphigus predisposes to increased mortality.

Table 13.4 Guide to interpretation of ANCA.

Result	Guide to interpretation
Positive C-ANCA with PR3 antibodies	Wegeners granulomatosis
Positive P-ANCA with MPO antibodies	Microscopic polyangiitis Churg–Strauss syndrome
Positive C-ANCA without PR3 antibodies	Inflammatory bowel disease Infection, malignancy
Positive P-ANCA without MPO antibodies	Vasculitis, connective tissue disease Infection, malignancy

ACETYL CHOLINE RECEPTOR ANTIBODIES, MYASTHAENIA GRAVIS AND THYMOMA

Myasthenia gravis is characterized by increased skeletal muscle fatiguability. Facial and bulbar muscle involvement may cause nasal speech and difficulty in swallowing. Generalized weakness occurs in approximately 85 percent of patients. Autoantibodies to the acetyl choline receptor (AChR) at the neuromuscular junction are detectable in 90 percent of patients. Myasthenia gravis is associated with thymoma (when anti-striated muscle antibodies may also be present) and other autoimmune diseases.

IMMUNOFLUORESCENCE STUDIES/BIOPSY

Detecting immunoglobulin and complement deposits in biopsies by means of fluorescent antibodies to these components may be helpful in the diagnosis of bullous skin disease, as mentioned above. Other indications include a variety of dermatological and renal diseases.

Lymphoproliferative disease

Many of the immunological tests required to investigate lymphoproliferative disease have already been mentioned and are used in combination with bone marrow and lymph node biopsies. A diagnosis of multiple myeloma is derived from the presence of two from three of the following: urinary or serum paraprotein (immunoglobulins detectable as a discrete band on electrophoresis and produced from a single clone of plasma cells); 10 percent plasma cells on bone marrow examination; and bone involvement on skeletal survey or bone scan.

IMMUNOGLOBULINS AND SERUM AND URINE PARAPROTEIN

A paraprotein should be sought when analysing total immunoglobulin levels. They may be detectable in both serum and/or urine, the presence of free light chains in the urine (Bence-Jones proteins) being particularly suggestive of a lymphoproliferative disease. High levels of serum paraproteins associated with reduced serum immunoglobulins (immunoparesis) is also suggestive of malignant disease. Low paraprotein concentrations, e.g. <10 g/L may occur in infections, inflammatory diseases and with monoclonal gammopathy of uncertain significance (MGUS). MGUS may progress to lymphoproliferative disease.

PHENOTYPING

Cellular phenotyping may contribute to the diagnosis of lymphoproliferative disease, for example chronic

lymphatic leukaemia (CLL). Similar techniques can also be applied to peripheral blood and bone marrow aspirates for the evaluation of myeloid disease.

KEY POINTS

- Immunodeficiency is uncommon but patients will present or be undiagnosed in ENT clinics. Targeting investigations to the relevant group, for example refractory sinusitis, will avoid missing cases of immunodeficiency.
- Immunological tests may help in diagnosis and monitoring of disease but must always be considered in association with clinical presentation and biopsy findings.
- Liaise with your clinical immunologist/immunology laboratory to ensure the appropriate tests are being requested. If clinical history is particularly suggestive of a disease, further tests may be required even in the presence of initial negative investigations.

Best clinical practice

- ✓ Immunological tests always need to be interpreted in the context of the clinical case.

Deficiencies in current knowledge and areas for future research

- The majority of current tests are performed on peripheral blood due to its accessibility. Tests that reflect activity at local surfaces, for example defensins, and tests that are more reflective of *in vivo* pathology, such as intracellular cytokine analysis, may enter clinical practice.
- Many patients that have severe, persistent, unusual and recurrent infections yet no immunological cause is identified. Advancing knowledge, particularly regarding the innate immune system, e.g. toll receptors, may account for such disease and diagnostic tests will subsequently follow.
- Increasing use of molecular diagnosis and development of tests looking at functional pathways will occur. It is becoming increasingly apparent that

individuals with the same genetic mutation may have diverse disease phenotypes, e.g. btk mutation associated with complete absence of B cells or IgG subclass defect. Identification of genetic polymorphisms may predict patients at risk of severe disease requiring a more aggressive management strategy.

- Tests are being developed that reflect patient response to treatment, e.g. antiviral drugs in HIV, or side effects to azathioprine, for example. This will help optimize treatments whilst minimizing harm.

SEARCH STRATEGY

The data for this chapter are supported by a Medline search using the key words immunodeficiency and ear/nose/throat. The classification of primary immunodeficiency is based on the report of the IUIS Scientific Committee.¹

INTRODUCTION: PRIMARY AND SECONDARY IMMUNODEFICIENCY

Primary and secondary immunodeficiency may both present with severe, recurrent, unusual or persistent infections with the specific defect influencing the type of presentation or organism involved. Primary immunodeficiency refers to rare deficiencies of the innate or adaptive immune system. Secondary immunodeficiency is commoner and reflects immunological defects secondary to other pathology including cancer and infections such as human immunodeficiency virus (HIV). It is, however, important to differentiate these two groups of conditions to allow initiation of the correct treatment which may, for both conditions, reduce morbidity and mortality. Features that may point to primary immunodeficiency include failure to thrive, a positive family history and associated autoimmune features, for example, idiopathic thrombocytopenic purpura (ITP). Lymphoproliferative disease may also be a complication.

Patients with immunodeficiency present to a variety of specialties, but particularly ENT and respiratory departments. A multidisciplinary approach is essential for both diagnosis and treatment. Deficiencies affecting most parts of the immune system are documented and those affecting T and B cells, phagocytes and complement will be

described along with certain specific diseases characterized by major immunological deficits. When managing immunodeficiency, liaison with a clinical immunologist is required at an early stage in each individual case. Infections in immunodeficient patients must also be treated with higher doses of antibiotics and for longer periods, compared to immunocompetent individuals.

PRIMARY IMMUNODEFICIENCY DISEASES

Combined immunodeficiency

SEVERE COMBINED IMMUNODEFICIENCY

Severe combined immunodeficiency (SCID) describes the most severe forms of primary immunodeficiency affecting both T and B lymphocytes. It has an incidence of 1/30–70,000 live births.² A variety of genetic defects, e.g. cytokine (interleukin (IL)-2, 4, 7, 9 and 15) receptor gamma chain, janus kinase 3 and recombination activation gene mutations, prevent T cell and also sometimes B cell and NK cell development and function. Untreated SCID leads to early death from overwhelming infection, typically within the first year of life.² Respiratory infections are common and include *Pneumocystis carinii*,

Cytomegalovirus pneumonitis and viral bronchiolitis. *Candida* frequently colonizes the skin, oropharynx and nappy area, and skin sepsis, e.g. *Staphylococcus*, may also be problematic. Other features compatible with SCID are failure to thrive and disseminated BCG infection. Once the diagnosis is suspected, antibiotics, anti-fungal and immunoglobulin therapy should be commenced. Live vaccines must be avoided and if blood transfusion is required it must be cytomegalovirus negative. Blood must also be irradiated to kill any donor lymphocytes that could cause graft versus host disease. Early bone marrow transplantation, prior to infection becoming established, is curative for some forms of SCID. Early experiences with gene therapy for cytokine receptor gamma chain SCID are also impressive.

Reticular dysgenesis is a form of SCID characterized by severe neutropenia as well as lymphopaenia. It reflects

aberrant stem cell development and follows autosomal recessive inheritance. Some defects, for example adenosine deaminase (ADA) deficiency and purine nucleoside phosphorylase deficiency, may present as a SCID but may also present later in life with recurrent infections accompanied by neurological disturbance in combination with bony defects (for ADA deficiency) or autoimmune manifestations (for purine nucleoside phosphorylase (PNP) deficiency) (Table 14.1).

X-LINKED HYPER IgM SYNDROME

X-linked hyper IgM (XHIM) syndrome results from defects in the gene for CD40 ligand (see Chapter 11, Defence mechanisms) which is expressed on T cells and whose interaction with B cells induces B cells to switch from producing IgM antibodies to IgG and IgA

Table 14.1 Disorders of T and B lymphocytes and antibodies.

Disease	Defect	Clinical	Laboratory	Treatment
SCID	Mutations affecting T and B cell development and function	Respiratory Candida Failure to thrive	Low lymphocyte count Low T/B cell number Reduced T cell proliferation Specific defects	Antibiotics Anti-fungals Immunoglobulin BMT Gene therapy
Hyper IgM syndrome	Mutations CD40 ligand on T cells needed for immunoglobulin class switching and T cell priming	Respiratory infections Diarrhoea Oral ulcers Tumours	Normal or high IgM Low IgG and IgA Neutropenia +/- Lack of CD40 ligand expression Mutations CD40 ligand	Cotrimoxazole Immunoglobulin BMT
X linked agammaglobulinaemia	Mutations in btk gene needed for B cell development	Sinusitis Otitis media Pneumonia Arthritis Meningoencephalitis	Absent/low B cells Low immunoglobulins Neutropenia +/- Btk mutations	Immunoglobulins Antibiotics
CVI	Most unknown	Sinusitis Otitis media Pneumonia Gastrointestinal infection Autoimmunity Granuloma Tumours	Low immunoglobulins B cells present	Immunoglobulin Antibiotics
Selective antibody deficiency	Unknown	Well Sinusitis Pneumonia	Low IgA Low IgG subclass Lack of response to immunizations	None Antibiotics Immunoglobulin
Transient hypogammaglobulinaemia newborn	Disparity resolution maternal IgG and IgG production	Well Bacterial infections	IgM low/normal IgG and IgA low	None Antibiotics Immunoglobulin

antibodies. This condition usually presents in infancy with upper and lower respiratory tract infections.³ CD40 ligand defects also result in poor T cell priming leading to infection with *Pneumocystis jirovecii* and *Cryptosporidium*. Recurrent oral ulcers are also common and may be associated with neutropenia. Regular immunoglobulin replacement and prophylactic co-trimoxazole are the cornerstone to management. Life expectancy is poor with <30 percent of patients alive at 25 years of age and major causes of death including *Pneumocystis jirovecii* pneumonia, liver failure and tumours. Bone marrow transplantation performed early in life offers the potential for a cure.

Predominantly antibody deficiency

Defects in B lymphocyte development and antibody production commonly produce recurrent bacterial infections presenting at any age. Antibody deficiencies are a spectrum ranging from the absence of a single antibody class of antibody, namely IgA, through to essentially no antibody (panhypogammaglobulinaemia). There are even certain individuals that have normal antibody levels but are unable to respond to specific microorganisms. Treatment, if required, is centred on intravenous immunoglobulin (IVIg) therapy, although concerns about supply and potential transmission of infections require the use of IVIg to be justified on an individual basis. Immunoglobulin therapy (0.6 g/kg/month) has been shown to significantly reduce the frequency of acute infections and improve lung function tests.⁴ [****] Intravenous and subcutaneous immunoglobulin administration appear to be equally beneficial whilst intramuscular replacement is less effective.^{5,6} [****] Home therapy programmes which involve self-administration, intravenous and subcutaneous, may enhance quality of life and allow patients optimal control of their disease.

X-LINKED AGAMMAGLOBULINAEMIA

X-linked agammaglobulinaemia (XLA) is characterized by a profound deficiency of B cells due to a mutation in the btk gene producing arrest of B cell development. Lymphoid hypoplasia with a lack of tonsils may be a diagnostic clue.⁷ Susceptibility to infection manifests as transplacentally transferred maternal IgG levels wane at four to six months, although some patients may not present until five years of age or older. Sinusitis, otitis media and lower respiratory infections are the most common infected sites with *Haemophilus influenzae*, *Staphylococcus aureus*, *Streptococcus pneumoniae* and *Pseudomonas*, the most frequent pathogens.⁸ Mycoplasma arthritis and enteroviral meningoencephalitis contribute both to morbidity and mortality. Treatment is based on immunoglobulin replacement and whilst low dose regimes may prevent severe acute bacterial infections, higher doses

may be required to prevent the development of bronchiectasis, chronic sinusitis and enteroviral infections.⁹

COMMON VARIABLE IMMUNODEFICIENCY

Common variable immunodeficiency (CVI) probably encompasses a variety of antibody deficiencies and a handful of genetic causes have been found to account for a small percentage of cases. It is characterized by recurrent bacterial infections. Patients have circulating B cells but are unable to secrete immunoglobulin resulting in hypogammaglobulinaemia. A family history occurs in approximately 20 percent of cases of CVI and IgA deficiency. Mean age at diagnosis is 30 years but, regrettably, symptoms are often present up to six years prior to diagnosis.¹⁰ Recurrent pneumonia and maxillary sinusitis are the commonest prediagnostic finding and chronic pulmonary complications may have already developed prior to diagnosis.¹¹ Recurrent bronchitis, sinusitis and otitis media, most frequently due to *Haemophilus influenzae* and *Streptococcus pneumoniae*, occur in 98 percent of patients. Seventy-five percent of patients also have pneumonia. Gastrointestinal infection, for example *Salmonella* and *Giardiasis*, is also common whilst septic arthritis and meningitis are recognized, but less frequent, complications. Over 20 percent of patients have associated autoimmunity, e.g. haemolytic anaemia and idiopathic thrombocytopenia. Granuloma and inflammatory bowel disease are also common. Non-Hodgkin's lymphoma occurs in <8 percent of patients and the risk of other malignancies, including squamous cell tumours and adenocarcinomas, is also increased. Life expectancy is reduced with 20-year survival rates of approximately 65 percent. Treatment is based on regular immunoglobulin therapy with aggressive and appropriate treatment of intercurrent infections.

SELECTIVE IMMUNOGLOBULIN IMMUNODEFICIENCY

This broad term includes isolated IgA deficiency, selective IgG subclass deficiency (normally IgG2) and specific antibody deficiency, or any combination of these. Diverse clinical presentations require management decisions to be made on an individual basis with the clinical phenotype ranging from normal health to recurrent otitis media and sinopulmonary infections.

IgA deficiency occurs in 1/600 Caucasians and it is important to screen those individuals who in addition have recurrent infections, for a functional antibody defect. Complete IgA deficient patients may also develop anti-IgA antibodies posing a risk of anaphylaxis on exposure to IgA via blood products.

A primary diagnosis of IgG subclass deficiency is based on a normal total IgG with low levels of one or more IgG subclasses. IgG subclasses are, however, reduced as part of other immunodeficiencies. In early childhood, normal

IgG subclass ranges may be difficult to define and IgG2 levels are frequently reduced. IgG2 deficiency may be associated with an inability to respond to polysaccharide antigens, for example pneumococcus, and one clue is that it is often associated with IgA deficiency.

Specific or functional antibody deficiencies refers to individuals who cannot mount an antibody response to a pathogen or immunization and can be present in individuals with normal or low levels of IgG. This most commonly occurs with pneumococcal antigens but the diagnosis can also be applied to patients who fail to respond to hepatitis vaccine.

TRANSIENT HYPOGAMMAGLOBULINAEMIA OF INFANCY

This condition reflects an imbalance between neonatal catabolism of maternal IgG that was transported across the placenta during the last trimester of pregnancy, and initiation of immunoglobulin synthesis by the maturing infant. A period may occur where infants have immunoglobulin levels in the immunodeficiency range and hence may be susceptible to infections. This condition is exacerbated by prematurity where the opportunity for maternal transfer of IgG is reduced. Infants require monitoring which should demonstrate initial production of IgM, followed by responses to vaccinations and rising levels of IgG. In cases of severe infection, immunoglobulin

therapy may be required during the period of immunodeficiency and a definitive diagnosis may only be made retrospectively.

Defects in phagocyte number and function

Phagocyte defects are characterized by early age of onset of recurrent infections with opportunistic bacterial and fungal infections. Neutrophil disorders may be divided into neutropenia reflecting decreased production (e.g. secondary to cytotoxics) or increased consumption of neutrophils (e.g. systemic lupus erythematosus (SLE)), and disorders of neutrophil function.¹² Neutrophil dysfunction may reflect defects of intracellular killing, for example chronic granulomatous disease (CGD), defects in the formation and function of neutrophil granules, for example Chediak-Higashi syndrome, or defective neutrophil adhesion, for example leukocyte adhesion deficiency (LAD). Defective cytokine signalling involving macrophages may also account for susceptibility to mycobacterial infections. Early diagnosis resulting in initiation of appropriate treatment, for example prophylactic antibiotics and antifungals, granulocyte colony stimulating factors (G-CSF) or bone marrow transplantation may improve survival. Several specific immunodeficiency diseases are detailed below (Table 14.2).

Table 14.2 Disorders of phagocyte number and function.

Disease	Defect	Clinical	Laboratory	Treatment
Severe congenital neutropenia	Mutations in G-CSF receptor in some cases	Septicaemia Meningitis Peritonitis	Absolute neutropenia Bone marrow myeloid hyperplasia with maturation arrest	G-CSF Antibiotics
Cyclical neutropenia	Neutrophil elastase 2 mutations	Oral ulceration Stomatitis Cellulitis	Neutropenia for 3–10 days every 15–35 days	Antibiotics
LAD	Mutations in CD18	Delay umbilical cord separation Stomatitis Otitis media Peridontitis Intestinal fistulas	Neutrophilia with infection Reduced CD18 expression	BMT (severe) Antibiotics
CGD	Defects in NADPH complex for reactive oxygen metabolites	Pneumonia Abscess Osteomyelitis Granuloma	Abnormal NBT test Abnormal phagocytosis and killing	Antibiotics Antifungals Bone marrow transplant
Leukocyte mycobacterial deficiency	IL-12, IL-12 R IFN- γ R	Disseminated Mycobacterial infection		IFN- γ in some cases BMT (severe)

SEVERE CONGENITAL NEUTROPENIA

Severe congenital neutropenia (SCN) is related to maturation arrest at the myelocyte to promyelocyte stage and both autosomal dominant and recessive forms as well as sporadic cases are recognized. Some patients have mutations in the G-CSF receptor gene resulting in hyporesponsiveness to G-CSF. SCN usually manifests in the first few months of life with overwhelming infections, for example septicaemia, meningitis, peritonitis and pneumonia. Other presentations include lymphadenitis, stomatitis, cellulitis and omphalitis with *Staphylococcus aureus* and *Pseudomonas* representing common pathogens. Life expectancy is increased with G-CSF therapy but transformation into acute myelogenous leukaemia or myelodysplasia occurs in 10 percent of cases.

CYCLICAL NEUTROPENIA

This condition reflects cyclical disturbances in bone marrow myelocyte production translating into recurrent neutropenia, often with a 21-day cycle. An autosomal dominant pattern of inheritance is recognized and mutations in the neutrophil elastase gene (ELA2) are described, although how this leads to pathology is currently unknown. Cyclical neutropenia typically presents in the first decade of life with episodic oral ulceration, stomatitis, fevers and cellulitis. Whilst this condition may improve with age, 10 percent of patients have fatal infections including pneumonia and peritonitis, or gangrene.

LEUKOCYTE ADHESION DEFECTS

Defects in adhesion molecules (see Chapter 11, Defence mechanisms), for example integrins (CD18 deficiency) and selectins, may disrupt neutrophil adherence to activated endothelium and migration to inflammatory sites. When an individual with leukocyte adhesion defects (LAD) encounters a pathogen, the bone marrow responds appropriately upregulating neutrophil production and release. However, these cells will not reach their destination, making individuals susceptible to overwhelming infection whilst exhibiting a profound neutrophilia.

CHRONIC GRANULOMATOUS DISEASE

Chronic granulomatous disease (CGD) is caused by mutations in the components of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex in phagocytes that produce reactive oxygen metabolites necessary to kill bacteria and fungi. CGD occurs in 1/200,000 live births with an X-linked recessive inheritance accounting for 70 percent of cases whilst the remainder are autosomal recessive.¹³ Seventy-five percent of individuals are diagnosed at less than five years of age,

in 4 percent the diagnosis is delayed to the third decade or later; the oldest patient was 69 years at diagnosis. The clinical picture is dominated by pneumonia, abscesses, suppurative rhinosinusitis and osteomyelitis. *Aspergillus*, *Staphylococcus*, *Burkholderia* and *Serratia* are the common pathogens. Prophylactic anti-bacterials (Cotrimoxazole) and anti-fungals (Itraconazole) appear to reduce the incidence of infection. *Aspergillus* infection is the most frequent cause of death and established infection requires aggressive treatment. Granulomatous complications may lead to gastric outlet or urinary obstruction and may be helped by corticosteroids. The role of interferon (IFN)- γ therapy in CGD remains controversial but is helpful in some cases. Bone marrow transplantation may be curative but carries a 10 percent mortality rate.

LEUKOCYTE MYCOBACTERIAL DEFECTS

This covers mutations in IFN- γ receptor, IL-12 and IL-12 receptor, which are all required for defence against intracellular microbes by macrophages, and effective granuloma formation. Patients are susceptible to disseminated non-tuberculous mycobacteria, BCG, *Salmonella* and *Listeria monocytogenes*.

Complement deficiencies

Genetic deficiencies have been documented in most components in the classical, alternative and terminal complement pathways. Each defect is associated with a specific immunological presentation, for example recurrent infections, systemic lupus erythematosus (SLE) or angioedema. Mannan binding lectin (MBL) interacts with the complement system and deficiencies of MBL also predispose to recurrent bacterial infections, for example otitis media. MBL polymorphisms also influence the clinical expression of other immunodeficiencies, for example CGD, and affect the susceptibility to certain pathogens such as meningococcus and aspergillus (Table 14.3).

CLASSICAL PATHWAY

C1q, C1r, C2 and C4 deficiency

Defects of the classical pathway, for example C1q, C1r, C2 and C4 deficiency, have an autosomal recessive mode of inheritance. They are associated with an SLE-like syndrome, rheumatoid disease and recurrent infections. Treatment is centred on management of the connective tissue disease with antibiotics for infection.

C1 esterase inhibitor deficiency

C1 inhibitor is part of the classical pathway but in contrast to the above, its deficiency (hereditary

Table 14.3 Disorders of complement pathway.

Disease	Defect	Clinical	Laboratory	Treatment
Clq, C1r, C2 and C4 deficiency	Genetic defects (AR)	Pyogenic infections	Reduced CH50 Low level component	Antibiotics
C1 esterase inhibitor deficiency	Absence or dysfunction C1 esterase (AD)	Angioedema	Reduced C1 esterase inhibitor levels (85%) Low C3 and C4 in attack	C1 esterase concentrate Danazol Tranexamic acid
C3, factor H and I deficiency	Genetic defect (AR)	Pyogenic infection	Reduced AP 50 Low level component	Antibiotics
Factor D and properdin deficiency	Genetic defects (AR/XL)	Meningitis	Reduced AP 50 Low level component	Antibiotics
Terminal complement	Defects in C5–9	Meningitis Gonorrhoea	Reduced CH50 and AP50 Low level component	Antibiotics
MBL	Point mutations in MBL, low levels MBL	Otitis media	Low levels MBL	Antibiotics

angioedema (HAE)) is characterized by autosomal dominant inheritance and recurrent attacks of angioedema either externally or internally. This can result in potentially fatal epiglottic and laryngeal oedema or oedema of the gut causing recurrent abdominal pain. Attacks often start in adolescence and may be precipitated by physical pressure, for example dental work and oral contraception. Patients have an absent or dysfunctional C1 inhibitor. Acute attacks resolve quickly with C1 inhibitor concentrate. Prophylactic measures for HAE include danazol, tranexamic acid and preoperative C1 esterase concentrate to cover surgery. In contrast to the oedema of immediate allergic reactions (Type 1 hypersensitivity), the oedema of HAE evolves less quickly, is never associated with urticaria and does not respond to adrenaline but is associated with a low plasma C4.

ALTERNATIVE PATHWAY

Alternative pathway defects, for example C3, Factor H and I deficiency, follow autosomal recessive inheritance and predispose to recurrent pyogenic infections. Factor D (autosomal recessive) and Properdin (X-linked) deficiency, however, predispose to neisserial infections in a manner similar to terminal pathway defects.

TERMINAL PATHWAY

Terminal pathway defects (C5–C9) pose an increased susceptibility to neisserial infections with both meningococcus and gonococcus. Meningitis may actually take a less fulminant form than in immunocompetent individuals. However, optimum immunization should be achieved whilst prophylactic antibiotics are usually recommended although evidence is lacking.

Other well-defined immunodeficiency syndromes

WISKOTT ALDRICH SYNDROME

Wiskott Aldrich syndrome (WAS) results from defects in the WAS protein which appears to be involved in cytoskeletal reorganization resulting in defective signal transduction, cell motility and phagocytosis. This X-linked disease is characterized by recurrent infections (particularly otitis media), eczema, thrombocytopaenia, autoimmune phenomena and increased risk of lymphoproliferative disease.¹⁴ IgG levels may fall with increasing age, particularly impaired pneumococcal antibody responses. Treatment is based on prophylactic antibiotics, immunoglobulin replacement therapy, splenectomy for thrombocytopaenia and platelet transfusions for life threatening haemorrhage.¹⁵ Median survival is around 15 years of age. Bone marrow transplantation remains a realistic option for children under five years with survival rates becoming poor in later life (Table 14.4).

ATAXIA TELANGIECTASIA

Ataxia telangiectasia (AT) is an autosomal recessive disorder caused by mutations in the ATM gene which encodes a large protein kinase that detects DNA breaks, facilitating DNA repair. Patients exhibit a particular sensitivity to radiation such that immunoglobulin and T cell receptor genes are subject to frequent chromosomal breakages, inversions and translocations. It is clinically characterized by immunodeficiency, oculocutaneous telangiectasia, progressive cerebellar disease and a susceptibility to cancer. Immunodeficiency may be progressive and is associated with reduced IgA and IgG2 levels with

Table 14.4 Other well-defined syndromes.

Disease	Defect	Clinical	Laboratory	Treatment
WAS	Mutations in WASP	Bacterial infections Eczema Thrombocytopaenia Autoimmunity Lymphoma	Low IgM Falling IgG Low pneumococcal response Lymphopaenia Low mean platelet volume	Antibiotics Immunoglobulins Splenectomy BMT
AT	Mutations in ATM gene which detects DNA breaks in T and B cells	Sinopulmonary infections Telangiectasia Cerebellar ataxia Cancer	Low IgA and IgG2 Poor response polysacharride	Antibiotics Immunoglobulins
Chromosome 22q11.2 deletions	Defect unclear Abnormal differentiation of branchial arches	Viral infections Hypocalcaemia Dysphagia	T lymphopaenia Reduced T cell proliferation	Antibiotics
XLP	SAP and SLAM gene mutations causing lymphocyte proliferation post EBV	Bacterial infections Fulminant EBV Aplastic anaemia Lymphoma	Agammaglobulinaemia to hypergammaglobulinaemia	BMT
Hyper IgE syndrome	Unknown	Pneumonia Pneumatocele Abscess Eczema Abnormal facies Bony abnormalities	Raised IgE	Antibiotics Anti-fungals
Autoimmune lymphoproliferative syndrome	Defects in apoptosis, e.g. Fas, Fas ligand	Lymphadenopathy Organomegaly	Defective apoptosis	Cytotoxics BMT
Chronic mucocutaneous candidiasis	Mutations in AIRE	Mucosal candida Endocrinopathy Autoimmunity	Reduced T cell proliferation to candida	Fluconazole

failure to respond to polysaccharide antigens. Recurrent bacterial sinus and pulmonary infections are common and may be exacerbated by aspiration and malnutrition. Twelve to fifteen percent of patients develop lymphoproliferative disease with other malignancies, for example adenocarcinoma also increased.

DI GEORGE SYNDROME/CHROMOSOME 22 DELETIONS

Di George syndrome (cardiac anomalies and parathyroid and thymic hypoplasia with immunodeficiency), Velo-cardiofacial syndrome (cardiac anomalies, hypotonia, palatal anomalies and mild developmental delay) and cardiac defects, abnormal facies, thymic hypoplasia, cleft

palate and hypocalcaemia-22 (CATCH-22) are all associated with 22q11.2 deletions. These specific gene defects disrupt differentiation of the branchial arches and the clinical phenotype of these conditions may blend. Immunodeficiency does not correlate with a specific clinical presentation and needs to be assessed on an individual basis.¹⁶ T cell lymphopaenia is common and can be associated with both impaired T cell and antibody function. Recurrent infections are common and viral infections, such as *Varicella*, *Parainfluenza* and *Rotavirus*, may be particularly severe. Conductive hearing impairment occurs in 45 percent of cases and may be associated with otitis media and speech delay.¹⁷ Sensorineural hearing loss is also reported but may partly reflect

peri-natal ischaemia. Persisting feeding difficulties related to cleft palate, increased depth of nasopharynx and pharyngo-esophageal dysmotility are common.

X-LINKED LYMPHOPROLIFERATIVE SYNDROME

X-linked lymphoproliferative syndrome (XLP) is caused by mutations either in the SLAM associated protein (SAP) gene whose protein is expressed on T cells, or its counterpart the SLAMF gene, which encodes a costimulatory receptor on T and B cells.¹⁸ In XLP, Epstein Barr virus (EBV) infected B cells may trigger uncontrolled polyclonal T and B cell proliferation and immune dysregulation. Patients may present with a clinical picture resembling common variable immunodeficiency (CVI). Hypogammaglobulinaemia may actually predate EBV infection in one-third of cases. Other presentations include fulminant EBV infection with diffuse lymphadenopathy, hepatitis and bone marrow failure, aplastic anaemia and B cell lymphoma. Prognosis is generally poor although immunoglobulin therapy containing antibodies to EBV may potentially help those patients diagnosed prior to primary EBV infection. Bone marrow transplantation has been curative in some cases.

HYPER IgE SYNDROME

The genetic basis of this autosomal dominant inherited multisystem disorder is unclear.¹⁹ Hyper IgE syndrome is characterized by recurrent skin and pulmonary abscesses, eczema and extremely high IgE levels. *Staphylococcus aureus* and *Haemophilus influenzae* pneumonia are common and may lead to pneumatocele formation with subsequent superinfection with *Pseudomonas aeruginosa* and *Aspergillus fumigatus*. Opportunistic infection including *Pneumocystis jirovecii* pneumonia and chronic candidiasis may also occur. Associated nonimmunological conditions include delay of shedding of primary teeth due to lack of root resorption, abnormal facies with facial hemihypertrophy, prominent forehead, deep-set eyes, broad nasal bridge, wide fleshy nasal tip, mild prognathism and high arched palate. Bone fractures, hyperextensibility and scoliosis can also be features.

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

Autoimmune lymphoproliferative syndrome (ALPS) is due to defects in genes encoding proteins that regulate apoptosis (see Chapter 11, Defence mechanisms), for example Fas, Fas ligand and caspases. The resultant failure of control of programmed cell death manifests as lymphoid proliferation with enlarged lymph nodes and spleen, B and T cell lymphomas and autoimmune phenomena. A characteristic immunological finding is the presence of double negative T cells (CD3⁺ CD4⁻ CD8⁻).

CHRONIC MUCOCUTANEOUS CANDIDIASIS

This condition is characterized by persistent candidiasis affecting the skin, nails and mucosa. It contributes to a spectrum of disease associated with multiple endocrinopathies involving the parathyroid, adrenal glands, thyroid, pituitary and ovaries and autoimmune phenomena, for example vitiligo and haemolytic anaemia. The disease may be known as autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) and be due to mutations in autoimmune regulator gene (AIRE) which effects immune tolerance.²⁰ The immunological defects are poorly defined but include reduced T cell proliferative responses.²¹ Fluconazole treatment may be effective for Candidiasis.

KEY POINTS

- Primary immunodeficiency is a rare disease but early diagnosis and treatment improves outcome.
- Primary immunodeficiency can target most parts of the immune system and specific defects are associated with clinical presentation.
- Always consult your local immunologist as he/she should be aware of new developments.

Best clinical practice

- ✓ Consider immunodeficiency if history of recurrent or unusual infections.
- ✓ Early liaison with a clinical immunologist can reduce long-term complications of immunodeficiency.

Deficiencies in current knowledge and areas for future research

- The definition of primary immunodeficiency may be challenged with advancing knowledge of disease pathogenesis. Disease could be classified according to innate immunological molecular defect or clinical presentation dominated by infection. This is illustrated by the finding of an immunological cause (defective TAP genes resulting in low expression of surface HLA class I molecules) causing a condition resembling Wegeners granulomatosis, a disease that would traditionally not be considered to be an immunodeficiency.²²

- New immunodeficiencies will be characterized. A new form of X-linked dominant hereditary angioedema with normal C1 inhibitor levels has already been described although the cause is yet undefined.²³ Knowledge of such diseases will provide insights into the immunopathogenesis of disease.
- Whilst major advances in understanding the genetic cause of disease have occurred in the last decade, new treatments are still required. Advances in the current practices of transplantation and gene therapy will occur, along with the use of biological agents and drugs targeting intracellular signalling. Experimental animal models suggest injection of B-lys (a TNF-receptor superfamily ligand) may actually increase total immunoglobulin levels and specific antibody responses in immunodeficient mice.
- Increasing understanding of the psychological impact of a diagnosis of immunodeficiency and its interaction with disease will occur which may translate into better quality of life.

SEARCH STRATEGY AND EVIDENCE-BASE

The data in this chapter are supported by a Medline search using the key words: rheumatology, rheumatoid arthritis, osteoarthritis, spondylarthropathy, SLE, Sjögren's syndrome, scleroderma, polymyositis, vasculitides, systemic lupus erythematosus, Paget's disease, Behçet's syndrome, Churg–Strauss syndrome, sarcoidosis, relapsing polychondritis, amyloidosis. Evidence throughout is level 4.

INTRODUCTION

The ENT manifestations of rheumatological diseases in the ear, nose and throat are diverse and although they are relatively uncommon, it is important that they are considered in the differential diagnosis of many conditions and are not overlooked (see **Table 15.1**). This chapter will not discuss the treatment, except where it may cause symptoms, for these are many and varied and are usually monitored by the physician. They are covered in a standard textbook on the subject, such as the *Oxford handbook of rheumatology*.¹ This chapter will look at the possible relationship between the diverse range of rheumatological conditions along with various ENT

diseases and examine the validity of many of the proposed links that have been advocated between them and examine whether they are coincidental or not.

The word *rheum* comes from the Greek meaning to flow down as of mucus. It was applied to the musculoskeletal system following its usage in rheumatic fever, which presented with upper respiratory tract symptoms. Many diseases give rise to both ENT manifestations and musculoskeletal problems, and they range from the common cold to severe necrotizing granulomata. This presents a problem to the ENT surgeon in the differential diagnosis of ear, nose and throat symptoms in patients who come with nonspecific musculoskeletal complaints. Examination of the ear, nose and throat may show nonspecific

changes prior to the development of florid signs. The skin may also be involved in some of these conditions. An ENT surgeon may be asked to see a patient with an established rheumatological condition, and be asked if there is any connection between it and, say, sensorineural deafness. As both sets of conditions may be common, particularly in the elderly, it may be easy to falsely link the two conditions.

There are essentially four relationships between the two sets of conditions; a chance finding, the natural occurrence, an association and a direct causal relationship. It is easy to confuse the first two relationships with the last two. This happens in many areas and is particularly true for Ménière's syndrome where a large number of tests have been advocated on poor epidemiological evidence.

SYMPTOMS AND SIGNS

Ear

Symptoms may be unilateral or bilateral and depend on whether the middle ear, inner ear or both are involved. Hearing loss is the commonest complaint but all symptoms, including Menière's-like phenomenon, have been described. If the ear is abnormal, the commonest abnormality is a middle ear effusion. When the mucosa is ulcerated and scarred, adhesive otitis media results in a fixed middle ear mass. This is virtually impossible to correct surgically. Sensorineural hearing loss can either be fluctuant as in Wegener's granulomatosis, particularly prior to or as a response to treatment, or progressive as in some cases with rheumatoid diseases, particularly systemic lupus erythematosus (SLE). It may be due to either a vasculitis or deposition of immune complexes.

Oral cavity and temporomandibular joint

Aphthous ulceration in the oral cavity and pharynx frequently results in extremely painful, small, punched-out white lesions. If the ulcers are deep and large, cercarial scarring results. When this extends into the oesophagus, stenosis and dysphagia may be extreme. If the salivary glands are involved, the mouth may be dry and dental caries result from this. Patients complain of a foul taste. Burning may be a problem but is frequently a nonspecific complaint of patients, particularly affecting women in the sixth decade. The major salivary glands may be palpable. Pain and reduction of movement can occur in the temporomandibular joint (TMJ). This fluctuates with the severity of the disease and rarely results in ankylosis.

Larynx and pharynx

Patients can have hoarseness due to involvement of the synovial joints in the larynx. Salivary gland involvement gives rise to lowering the production of saliva and this can produce a feeling of a lump in the throat or dysphagia. If there is ulceration in the subglottis, hemoptysis and crusting may occur. This heals by fibrosis and stenosis. Poor movement of the vocal cords occurs particularly when there is involvement of the synovial joints of the arytenoids cartilages. Rarely, plaques may be seen in amyloidosis.

Nose

The symptoms range from blockage alone to a serosanguinous discharge and crusting. Facial pain is usually a symptom of active disease but may occur with an

intercurrent infection. The nose may be affected by ulceration and granulomata with and without haemorrhage. Mucus will crust on denuded areas, or on fibrotic atrophic sites. Septal perforation and nasal collapse may also develop. Nasal bone cysts are very uncommon and have been described in sarcoidosis.

Lymphadenopathy

Nonspecific lymphadenopathy can accompany connective tissue diseases. Sarcoid produces a granulomatous lymphadenopathy as part of the condition, whereas the generalized inflammation in SLE and Sjögren's syndrome, for example, results in a higher rate of lymphoma. Any unexplained and persistent lymphadenopathy must be taken seriously and investigated appropriately.

Investigations

Most patients will have been investigated already, but some patients will present to the ENT surgeon or may no longer be under the care of the physician. As up to one-third of the patients may have anaemia, it will be worth performing a full blood count if the patients are lethargic. The erythrocyte sedimentation rate (ESR) or equivalent will often be raised in suspected vasculitis or in chronic diseases. Acute phase proteins are often raised in inflammatory conditions. The raised ESR may relate to the presence of autoantibodies.

Serological tests are the most useful and may be diagnostic for rheumatoid arthritis. Most laboratories run a batch of screening tests using histofluorescence and measure antibodies directed at different parts of the cell. Two cells are used, immortalized epithelial cells and polymorph leukocytes. Perhaps the most surprising connection between the connective tissue diseases and ENT is the use of the immortalized HEP-2 (human epithelial type 2 cells) cells as the substrate. These cells were derived from a human laryngeal carcinoma removed from a patient in the USA. The staining patterns help determine the enzyme-linked immunosorbent assay (ELISA) tests undertaken subsequently and these give a quantitative result.

Polymorph leukocytes are used for the presence of anti-neutrophil cytoplasmic antibody, and this test is probably the most useful one. It has two patterns, the perinuclear and the cytoplasmic patterns. The cytoplasmic pattern is found in Wegener's granulomatosis but may be raised in other vasculitides.² This study examined 871 sera that were positive in 10/11 (90 percent) of the active cases of Wegener's granulomatosis and there was a perinuclear positive pattern in 9/22 (40 percent) of patients with Sjögren's syndrome. It was occasionally raised in other conditions. Antibodies to proteinase 3 (PR3) from the polymorph leukocyte may be raised. The antibodies can disappear during treatment, and so levels

may be used as an indicator to monitor the disease but it should not be used in isolation as it is not accurate on its own. None of the tests is diagnostic but positive tests confirm connective tissue diseases.

A serum angiotensin converting enzyme level may be raised in sarcoidosis. Protein electrophoresis may help in excluding the 15 percent of patients with amyloid who have an underlying myeloma.

Biopsies of lesions and minor salivary glands may help in the diagnosis of these conditions. Some studies have looked at physical findings, such as nasal septal ulcers and perforations.³ Biopsy did not help in the diagnosis of 71 patients, six had Wegener's granulomatosis and one had sarcoid on further testing. If granulomata are found, the diagnostic yield is higher and may help in the diagnosis.⁴ The author undertakes biopsies in the operating theatre using an endoscope and samples any granulomata in preference to ulcers and perforations.

Imaging

CT and MRI have a role in evaluating the extent of disease in the organ affected but are usually unable to tell the current activity. An MR scan is best for determining inflammatory activity in joints but may show nonspecific changes in the nose and sinuses. CT is best for demonstrating bony erosion and new bone formation. Similar, but far more pronounced, changes are found when patients have a T-cell lymphoma. Patients with Wegener's granulomatosis have residual changes after the acute phase has been treated and this can confuse the clinician. Bony erosion may also occur in sarcoidosis and bone cysts can develop in the nasal bones very rarely. Imaging is helpful but is not diagnostic except in scleroderma when the contrast study demonstrates the oesophageal lesion.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is a persistent, fluctuating, destructive and chronic inflammatory condition, which produces synovitis and joint destruction. Women are more frequently affected than are men, and pregnancy improves the condition. There is a familial predisposition and HLA-DR1 and 4 are found more frequently than expected. It is a symmetrical disease affecting the small synovial joints. It may affect the cervical spine and great care must be taken when such patients have general anaesthesia as damage to the spinal cord is possible. Morrell MacKenzie first described this condition affecting the joints of the adult larynx. Similar but less pronounced changes occur in juvenile cases. A post-mortem study of five patients showed that it affected the synovial joints of the larynx and other surrounding structures.⁵ Symptomatic involvement may occur in 25 percent of patients and up to 80 percent have asymptomatic involvement.⁶ The pathology

ranges from synovial involvement of the small joints through to ankylosis. Rheumatoid nodules may occur in the larynx and necrosis and involvement of the recurrent laryngeal nerves have been described. The TMJ may also be involved by the disease and is usually dealt with by the maxillofacial surgeons.⁷

Both conductive and sensorineural hearing loss may occur but the commonest finding is a hypermobile tympanic membrane and is contrary to expectation. This occurred in 25 percent of patients and 8 percent of controls.⁸

Lymphocytes are not antigen specific. Attention has moved away from the T cell being the most important cell to the increasing importance of macrophages and fibroblasts in the pathogenesis. They induce lymphoid aggregations that are micro-anatomical structures similar to lymph nodes. They produce cytokines such as interferon (IFN)- γ , which delay apoptosis and perpetuate the inflammation.⁹

OSTEOARTHRITIS

This degenerative condition may give rise to problems in any synovial joint but rarely affects the jaw joint. Cervical spine disease may present with neck pain that can be referred to the cranium. Patients confuse the pain with sinusitis but the symmetrical distribution and lack of any nasal symptoms rule this out. Patients with facial pain should have their neck examined carefully. Radiology and an MR scan of the affected areas, particularly the neck, may be helpful.

SPONDYLARTHROPHY

Ankylosing spondylitis is the most common condition. It is associated with nonspecific complaints in the head and neck but the literature does not reveal any obvious associations.

SLE

SLE is a multifactorial condition with a large number of different autoantibodies. Clinical classification includes a group with oral ulceration. Aphthous ulceration occurs in one-third of patients and so undiagnosed patients may present to the dental, maxillofacial and ENT surgeons. The diagnosis should be considered in all cases of multiple oral ulcers that fail to heal. A polyarteritis may cause a vasculitis that causes ulceration or an atrophic nasal mucous membrane and may result in a septal perforation. The symptoms of crusting and blockage are similar to Wegener's granulomatosis and there is overlap between the two conditions pathologically. Laryngeal involvement may also occur in a similar manner to rheumatoid arthritis.⁶ A recent study of ear involvement compared

43 patients with 50 age-matched controls.¹⁰ It showed that one-quarter of patients have a greater hearing loss in higher frequencies compared with controls. Overall, approximately three-quarters of the patients have some manifestations in the head and neck. Non-Hodgkin's lymphoma is more common in these patients than in the normal population and so unexplained and persistent cervical lymphadenopathy should be investigated promptly.

SJÖGREN'S SYNDROME

This is either a primary condition or it can be part of a generalized rheumatological condition. While a dry mouth and eyes are common, it may also result in hoarseness because of dryness and frequent throat clearing. Nasal symptoms are described with dryness, blockage and crusting. The condition is an immune-mediated chronic inflammatory disease of the salivary and lacrimal glands. The lymphocytic infiltration and inflammation lead to acinar destruction. Various autoantigens are found and include salivary duct antibodies. Nonspecific autoantibodies are present when it complicates autoimmune deficiency syndrome (AIDS) (e.g. anti-nuclear antibodies to antigens Ro and La). Loss of regulatory T cell function results in a polyclonal B cell proliferation and production of autoantibodies. The ENT surgeon may be asked to diagnose the condition with an intra-oral salivary gland biopsy, which can be undertaken under local anaesthesia infiltrated into the lower lip. The condition must be differentiated from other causes of diffuse parotid gland enlargement. Sjögren's syndrome is associated with a 40-fold increase in the development of lymphoma. The architecture of the lymphatic aggregations in the glands is similar to the germinal centres in lymph nodes.¹¹ Any lymphadenopathy must be investigated with fine needle aspiration cytology (FNAC).

SCLERODERMA

This heterogeneous disease affects women more commonly than men. The primary lesion is the formation of extra collagen. While there are many variations, both localized and diffuse, localized skin disease accounts for 60 percent of the cases. Raynaud's phenomenon is often the earliest presentation. The oesophagus is involved later, which may present as dysphagia to an ENT surgeon. The barium swallow has characteristic diffuse changes with cicatrization, often along a long segment.

POLYMYOSITIS AND DERMATITIS

There are many nonspecific symptoms other than the neck symptoms, the most common complaint is arthralgia in the larynx. The examination rarely adds anything further.

VASCULITIDES

While the rheumatologists and renal physicians categorize conditions by the size of the vessels involved, ENT surgeons group conditions by the extent of the inflammatory response – granulomata formation (**Figure 15.1**, **Table 15.2**). We have recently reviewed the classification of the specific and nonspecific nasal granulomata.¹² Wegener's granulomatosis is the most common multi-system disease and is seen at some time by every ENT

Figure 15.1 (a) and (b) The characteristic granulomata from a nasal biopsy removed from a patient with sarcoidosis. Histologically these are nonspecific but there is no caseation here and (b) shows giant cells and calcification. The latter is called a Schaumann body (Courtesy of Dr A Warfield).

surgeon (**Table 15.3**). The clinical division is split into limited disease and generalized disease when the kidney is involved. The lymphocyte response may initiate the vasculitis secondarily through the inflammatory chemokines. The lymphocyte response is commonly divided into a Th1 or a Th2 response by the cytokine profiles. Allergic diseases are driven by Th2 helper lymphocytes and the granulomatous diseases by a Th1 response. This is an over-simplification for there is evidence of a Th2 response in the nose in Wegener's syndrome while a Th1 response occurs in the blood and the kidney.¹³ This suggests that the end organ is important in the type of inflammatory response.

Table 15.2 Diagnostic paradigms – ENT surgeons compared with rheumatologist and renal physicians or granulomata versus vasculitides.

ENT surgeons	Physicians
Granulomata	Vasculitis
Specific or infectious	Large vessel
Tuberculosis	Giant-cell arteritis (temporal)
Syphilis	Takayasu
Leprosy	Medium
Rhinoscleroma	Classical polyarteritis nodosa
Leishmaniasis	Kawasaki's
Nonspecific or noninfective	Small
Wegener's	+ immune deposits
Sarcoid	Henoch–Schönlein purpura
Pyogenic granuloma	Cryoglobulinemia
Malignant	Goodpasture's disease
T cell lymphoma (lethal midline)	SLE
	– immune deposits
	Microscopic polyangiitis
	Wegener's
	Churg–Strauss syndrome

Table 15.3 System involvement in Wegener's granulomatosis.

	%
Nose	
Intranasal	80–95
External	25–40
Ear	
Middle	25–40
Inner	5–15
Larynx	25–40
Lung	80–90
Kidney	40–65
Eye	25–40
Musculoskeletal	25–50
Gastrointestinal	5–15

This table is taken from published studies. The variations reflect the different specialties that report patients.

Wegener's granulomatosis typifies all that may go wrong in rheumatological diseases, together with the variability of the severity of the condition. It is the condition with which ENT surgeons have the greatest familiarity as over 50 percent of patients have nasal symptoms on presentation¹⁴ and primarily complain of crusting, nasal obstruction, epistaxis and whistling from a septal perforation (**Figure 15.2**). The condition is considered in Chapter 130, Granulomatous conditions of the nose. Series range from a few cases to over a hundred. The author has between 30 and 40 under review at any one time. The vast majority of patients have nasal involvement. Those with middle ear involvement usually also have the nasal manifestations. Patients may present with a fluctuating sensorineural hearing loss and this often recovers on treatment.¹⁵ Nasal surgery, other than a biopsy, should be avoided in active Wegener's granulomatosis as it will induce adhesions. Biopsying normal looking nasal mucosa is of no value.^{3, 14} Reconstruction of the nose should be undertaken at least one year after the disease is inactive and no medication is required. Airway support with a tracheostomy is required if the subglottic stenosis is severe.

CRYSTAL ARTHROPATHIES

Gout is the most common condition and has a number of causes, including familial, and it is more common in men. The pinna may have tophi in patients who have a very high and untreated uric acid. This is rare now that the condition is better managed. The condition may affect the TMJ very rarely. Tophi have been described in the larynx, and may cause hoarseness. If these ulcerate, uric acid may be demonstrated in the sputum.⁶

SLE

The skin of the nose and nasal vestibule can be involved but this is usually long after the diagnosis has become apparent through its other manifestations. The manifestations are similar to Wegener's granulomatosis but are milder and less common.

PAGET'S DISEASE (OSTEITIS DEFORMANS)

Paget's disease is a common condition which occurs in 5 percent of the population over 60. It varies in severity and it involves the pelvis, long bones and the skull and is associated with various medical problems due to excessive new bone, which is vascular. When it involves the base of the skull, it gives rise to tinnitus, deafness and dysequilibrium in addition to headache. The deafness is sensorineural or may be mixed.^{16, 17} The middle ear may be reduced in volume by new bone, the bony changes may affect the ossicles including stapedial fixation, and fibrosis

Figure 15.2 The changes in crusting found inside the nose from a patient with active Wegener's granulomatosis: (a) shows early changes with an angry mucosa and mucous hypersecretion; (b) demonstrates the end result of gross activity.

Figure 15.3 A CT scan taken of a patient with Paget's disease of the base of the skull, the patchy new bone can be seen throughout. Courtesy of Mr D Proops.

may occur. Presbycusis is common in this age group and is exacerbated by the condition and the damage is probably multifactorial. The findings on a skull radiograph are characteristic (**Figure 15.3**) and MRI findings have been described.¹⁸

INFLAMMATORY DISEASES INCLUDING INFECTIONS

Acute sore throat and tonsillitis are the prodromal symptoms of rheumatic fever, which is fortunately rare now. Many acute infections have a generalized arthralgia as part of their picture. Most do not present to the ENT surgeon. Other chronic infections may present with laryngeal involvement such as tuberculosis.

BEHÇET'S SYNDROME

Although the eye manifestations are more commonly encountered, a Sjögren's syndrome-like picture is present in 10 percent of patients. The oral ulceration is often overshadowed by severe genital ulceration.

CHURG-STRAUSS SYNDROME

This is rare and typically presents with marked nasal polyposis, asthma and eosinophilia and patients are systemically unwell and may have a pyrexia of unknown origin. The management is similar to patients with severe polyposis.

© Hodder Arnold / Scott-Brown 7E

Figure 15.4 Examination of the nasal mucosa from a patient with sarcoidosis reveals apple jelly nodules.

OVERLAP SYNDROMES

These have a variety of features consistent with different aspects of connective tissue diseases but they are disparate enough that each patient with one or two of their features escapes categorization.

SARCOIDOSIS

The ear nose and throat may be involved in 5 percent of patients with sarcoidosis. They have the more severe manifestations of the disease and it tends to be more chronic than those presenting with erythema nodosum and hilar lymphadenopathy. The nasal mucosa has yellow submucosal nodules with a cobblestone appearance.¹⁹ If there is more advanced nasal disease it can have a similar appearance to Wegener's granulomatosis with crusts and mucus stagnation. A notable difference compared with Wegener's granulomatosis is that patients often feel well. Intracranial involvement is the most worrying complication as mortality is high and similar to cardiac involvement. The local cervical lymph nodes may be enlarged either alone or in combination with the intranasal involvement. The nose is most commonly involved and around 5 percent of patients have intranasal granulomata (**Figure 15.4**). The surrounding skin may

be involved and produce a violaceous discolouration with small nodules to large plaques known as lupus pernio. Bony involvement is rare, but lytic lesions may occur in the nasal bones. A chest radiograph shows hilar lymphadenopathy in approximately 80 percent of patients. Other ENT manifestations include lacrimal and salivary gland enlargement and facial palsy.

RELAPSING POLYCHONDritis

Tietze's syndrome is a relapsing polychondritis that affects the ribs and the cartilage of the external ear. The ear is very painful and the condition is distinguished from cellulitis by the distribution of the erythema, which spares the lobule. Deformity may result after resolution of the condition. For the diagnosis to be made, there have to be at least three of the following: chondritis of the pinna, the nose, the larynx or trachea, ocular involvement, a seronegative arthritis or a sensorineural hearing loss with or without vertigo.²⁰

AMYLOIDOSIS

Amyloidosis complicates patients with rheumatoid arthritis, juvenile arthritis and ankylosing spondylitis. The condition affects the larynx and tongue, but it has been described throughout the head and neck.²¹ Although the larynx is the most frequently affected area in the head and neck, it is usually involved in isolation.²² Patients have hoarseness. Deposits are found in the glottis and are firm red lesions lying under the mucosa. The tongue is usually involved in the generalized condition and sampling of abdominal fat by FNAC may confirm generalized amyloidosis. Macroglossia is rare and the tongue is firm and dry and some areas are raised and red. The biopsies of suspected areas are examined under polarized light, following staining with Congo red. The patients are grouped clinically into eight main types, primary, secondary, myeloma associated, isolated laryngeal, familial Mediterranean fever, familial, senile and dialysis-associated amyloidosis. The chemical composition groups the conditions into four. The vast majority of patients with ENT manifestations have IgG light chains in the deposit. Serum and urine analysis will exclude multiple myeloma.

DRUGS

Cyclophosphamide and azathioprine depress the marrow, which may result in oral infection and occasionally ulceration. The full blood count needs monitoring when patients are being treated with these. Aspirin may cause a self-limiting and dose-dependent tinnitus.

CONCLUSIONS

The rheumatological conditions are a heterogeneous group of diseases that may present to the ENT surgeon. The manifestations depend on the nature of the condition but every area in the head and neck may be involved. The role of the otorhinolaryngologist is to collaborate with clinicians who have an interest in this area. If there is evidence of abnormal mucosa, a biopsy can help to arrive at a diagnosis although this is not a very sensitive test, a positive result has a high predictive value. A negative biopsy does not exclude a vasculitis. In a patient with suspected Wegener's granulomatosis in whom the antineutrophil cytoplasmic antibodies (ANCA) test and biopsy are negative, the ANCA test should be repeated as it can take up to four years to become positive.¹⁴ It is sensible to transfer the care of the patient with the more active manifestations of these diseases to a subspecialist.

KEY POINTS

- Connective tissue diseases present to ENT surgeons.
- Wegener's granulomatosis has nasal manifestations in 90 percent of cases.
- Clinical management is best carried out by the appropriate physician.

Best clinical practice

- ✓ The role of the ENT specialist is in the diagnosis and monitoring of the condition.

Deficiencies in current knowledge and areas for future research

- Improved understanding of the pathophysiology is required, so that treatment can be improved.

SEARCH STRATEGY

The information in this chapter is supported by a Medline search of review articles using the key words of each of the organisms, upper respiratory tract infections focusing on bacterial causes, respiratory and nasopharyngeal microflora.

INTRODUCTION

With the rise in incidence of bacteria resistant to antimicrobial agents, the emergence of new and resurgence of old pathogens, the ability to recognize, investigate and treat infection appropriately is important for clinicians of all specialties.

The aim of this chapter is to summarize our current understanding of bacterial microorganisms of human importance, with specific emphasis on bacteria which are found as part of the normal microflora of and those responsible for, infections of the ear, nose and throat. Viruses and fungi will be covered in Chapter 17, Viruses and antiviral agents; and Chapter 18, Fungi.

Bacteria are single-cell organisms, seen by light microscopy, which unlike viruses are able to multiply by binary fission as well as survive outside other cells. Bacteria traditionally are separated on the basis of a combination of their cell wall structure using Gram stain, shape, results of simple biochemical reactions, for example catalase reaction, and more recently, ribosomal RNA analysis.

NORMAL MICROFLORA

After birth the nasopharynx of a newborn does not remain a sterile site for more than 48 hours, with rapid

acquisition of colonizing bacteria initially from the mother's genital tract, later followed by organisms which are ingested or from a carer's skin.

The normal indigenous flora consists of Gram-positive and -negative aerobic and anaerobic bacteria, including the oral streptococci, *Bacteroides* sp., *Corynebacteria* sp. and *Neisseria* sp. In addition, the nasopharynx can be colonized with potentially pathogenic bacteria such as *Streptococcus pneumoniae* (see **Table 16.1**). Carriage rates of these potential respiratory pathogens have been found to be higher in children during episodes of otitis media compared with healthy children.¹ [**] Both *Staphylococcus aureus* and *Streptococcus pyogenes* can be found in significant numbers in the nasopharynx of healthy adults (25 and 5 percent, respectively). Why these potential pathogenic bacteria can be carried without ill effect in the vast majority of people is not entirely clear. There seems to be a fine balance between underlying host risk factors which affect susceptibility to disease, the natural mucosal barrier to infection, the pathogenicity of the organism, and the presence of infection with other organisms, such as influenza A and respiratory syncytial virus.² [**] Also, some of the oral streptococci have been shown to inhibit the adherence of pathogenic bacteria, a phenomenon known as bacterial interference, and it is well recognized that the use of broad-spectrum antimicrobial chemotherapy can result in the reduction of these commensal

Table 16.1 Bacterial microflora of the nasopharynx.

Bacteria carried in the majority of people	'Respiratory bacterial pathogens' that may be carried asymptotically	Organisms associated with transient carriage (e.g. sick patients, antibiotic therapy)

organisms. Studies have shown that in otitis-prone children the numbers of oral streptococci are reduced and the numbers of *S. pneumoniae* and nontypable *Haemophilus influenzae* are increased.³ [**] A recent approach which warrants further investigation is to try and restore the bacterial flora back to normal using bacteriotherapy, for example the administration of nasal oral streptococci to prevent or reduce recurrent bouts of otitis media.^{4, 5} [****/*]

The nasopharyngeal flora can change with antibiotic therapy, underlying severe disease in the patient and hospitalization, with the replacement of the normal flora with aerobic Gram-negative bacilli (enterobacteriaceae) and the yeast *Candida albicans*.

GRAM-POSITIVE BACTERIA

Staphylococci

Staphylococci are Gram-positive, catalase-positive cocci that divide in two planes producing characteristic grape-like clusters on Gram stain. They grow well on most media at 18–40°C and will grow in the presence of sodium chloride and therefore are found on the skin and mucous membranes of warm-blooded animals. The genus contains 24 different species, only a few of which produce human disease. The coagulase test, which tests for the ability to coagulate plasma, separates the genus into two groups. *Staphylococcus aureus* is coagulase positive and is the main pathogenic species of the genus. There are 23 different coagulase-negative staphylococci. Other related genera are the micrococci and stomatococci, which rarely produce disease.

Staphylococcus aureus

Staphylococcus aureus is a coagulase-positive staphylococcus that has characteristically golden colonies when cultured on blood agar. At any one time 10–40 percent of the population carry *S. aureus* in their anterior nares and other skin sites, such as the perineum, with higher carriage rates in hospital inpatients.

Staphylococcus aureus has a number of virulence factors which enable it to invade human tissue, avoid the immune system and produce disease. They include capsular polysaccharide, collagen receptors and fibronec-tin-binding protein (promotes adhesion to host-cell surfaces), protein A (inhibits phagocytosis), coagulase, haemolytic toxins, staphylokinase (causes cellular damage) and a range of toxins.^{6, 7} [**]

Staphylococcus aureus is the most common cause for wound and skin sepsis, is responsible for invasive infections by haematogenous spread or direct invasion, producing focal infections, for example osteomyelitis, lung abscesses, and is the commonest organism recovered from blood cultures of patients presenting with bacteraemia/septicaemia in England and Wales. The isolation of epidemic methicillin-resistant *S. aureus* strains which are resistant to the β-lactam antibiotics and varying classes of other antibiotics has been increasing in clinical isolates in the UK over the last decade.

Staphylococcus aureus can also produce nonsuppurative disease either by the production of toxins outside the body which are then ingested, for example staphylococcal food poisoning due to enterotoxin production, or the production of the toxin at a site of colonization or minor infection, for example toxic shock syndrome due to staphylococcal toxic shock syndrome toxin which acts as a superantigen.

COAGULASE-NEGATIVE STAPHYLOCOCCI

The coagulase-negative staphylococci make up a large part of the normal skin and mucous membrane microflora, and there are 23 species of which *Staphylococcus epidermidis* is the commonest human isolate.

Most of the coagulase-negative staphylococci do not produce as many of the virulence factors as *S. aureus* and therefore are relatively nonpathogenic. They have been shown to be able to survive on inanimate objects, such as implants, by the production of an extracellular polysaccharide adhesin or biofilm in which they are protected from the immune system and multiply slowly.⁸ [**]

The coagulase-negative staphylococci were therefore generally thought to be nonpathogenic. Over the last two

decades the importance of these organisms has been recognized as the number of patients with prosthetic orthopaedic implants, intravascular lines and prosthetic valves has increased. They are a major cause for orthopaedic prosthesis failure, which usually results in implant removal and revision.

Streptococci (including enterococci)

Streptococci are Gram-positive catalase-negative cocci, which divide in one plane producing chains in broth culture. Streptococci are separated using a combination of haemolysis when cultured on blood agar and cell wall polysaccharide antigen detection using the Lancefield grouping antisera, biochemical tests and growth characteristics. Analysis of the ribosomal RNA has led to the separation of the faecal streptococci into the genus enterococci, producing the following groups:

- pyogenic streptococci (β -haemolytic streptococci);
- oral streptococci (viridans streptococci);
- anginosus-milleri group of streptococci;
- *Streptococcus pneumoniae*;
- enterococci (faecal or group D streptococci).

Apart from enterococci they are generally sensitive to all the β -lactam antimicrobial agents and the macrolide antibiotics.

Other closely related genera, which rarely produce human infections, are *Leuconostoc* sp., *Lactococcus* sp., *Pediococcus* sp., *Aerococcus* sp. and *Gemella* sp.

PYOGENIC STREPTOCOCCI (β -HAEMOLYTIC STREPTOCOCCI)

Streptococci which produce complete haemolysis of blood when isolated on blood agar (**Figure 16.1**) are separated using the Lancefield group antisera. The main human isolates group with A, B, C, D (enterococci see below) and G antisera.

Group A (*Streptococcus pyogenes*), C and G streptococci

Streptococcus pyogenes (group A streptococcus) is the most important of the β -haemolytic streptococci, producing the suppurative diseases of tonsillitis, skin sepsis, for example cellulitis and, rarely, severe necrotizing fasciitis, invasive disease, for example septicaemia, septic arthritis and streptococcal toxic shock syndrome.^{9,10} [**/*] Groups C and G streptococci can occasionally produce similar disease.^{11,12} [**]

They all produce two haemolysins, streptolysin O and S, streptokinase and hyaluronidase; in addition, *S. pyogenes* can produce erythrogenic toxins, proteinase and nucleases.

Groups A, C and G streptococci can be found colonizing the nasopharynx in apparently healthy

© Hodder Arnold / Scott-Brown 7E

Figure 16.1 Group A streptococcus (*S. pyogenes*) on blood agar demonstrating β -haemolysis and sensitivity to penicillin (PG 4).

subjects, in up to 11 and 1.4 percent for groups A and C, respectively.^{11,13} [**]

Nonsuppurative diseases also occur with group A streptococcal infection, such as glomerulonephritis, and rheumatic fever. Group A streptococci can be further separated by antisera raised to the M protein epitopes, M1, M18 and M3 serotypes are associated with more invasive disease and M3 and M18 with cases of rheumatic fever.¹⁴ [**] Several studies have shown that the epidemiology of group A serotypes is dynamic, with the replacement of one serotype with another in populations over time.¹⁵ [**] At the present time, rheumatic fever is rarely seen in the UK, but in the USA there have been outbreaks associated with the carriage of serotypes M3 and 18.¹⁶ [**]

Streptococcus agalactiae (group B streptococcus)

Group B streptococci rarely produce disease as they are not found in the nasopharynx but are the commonest cause of neonatal sepsis, and produce invasive disease in diabetics, alcoholic and immunocompromised patients.

STREPTOCOCCUS PNEUMONIAE (PNEUMOCOCCUS)

Pneumococci produce incomplete or alpha haemolysis on blood agar with draughtsman-like colonies, which are bile soluble and sensitive to the chemical agent optochin (**Figure 16.2**). In the diagnostic laboratory this characteristic is used to separate them from the oral streptococci which can be found in clinical samples. They are characteristically seen as capsulated diplococci in Gram stains of infected samples (**Figure 16.3**). The capsular polysaccharide is the main virulence factor and 90 different capsular polysaccharide serotypes have been described. They can be found as part of the normal nasopharyngeal flora particularly in the first two years of life, and are the commonest bacterial cause in all age groups for otitis media, sinusitis and pneumonia. Pneumococcal meningitis is more common in the very

© Hodder Arnold / Scott-Brown 7E

Figure 16.3 *Streptococcus pneumoniae* in Gram stain of sputum demonstrating characteristic Gram-positive diplococci.

young and elderly, where pneumococci gain entry to the meninges via haematogenous spread from respiratory infection. Pneumococci have been traditionally very sensitive to penicillins, but a rising incidence of penicillin resistance has been seen in the last decade, particularly in isolates from Eastern Europe, Spain and some parts of the USA, resulting in failures of penicillin therapy for meningitis. In view of the severity of disease produced by pneumococci and the emergence of antibiotic resistance, prevention of disease by vaccination has been widely studied. Until recently, polysaccharide vaccines which contained 23 of the commonest invasive serotypes were available but protection was short-lived with no protection for young children. Conjugate pneumococcal vaccines are now available (7, 9 and 11 valent) and have been introduced as part of the childhood vaccine schedule in the USA, and more recently in the UK, as they have been shown to reduce invasive disease, lobar pneumonia and 6–7 percent of cases of acute otitis media.¹⁷ [**/*] Further studies are required to determine the effect of these vaccines on the epidemiology of carriage strains.

ORAL STREPTOCOCCI (VIRIDANS STREPTOCOCCI)

The oral streptococci produce incomplete α -haemolysis when grown on blood agar, but are resistant to the agent optochin and are found as part of the normal oral and nasopharyngeal flora. They occasionally cause local disease, such as tooth decay and dental abscesses, but more importantly, they are the commonest cause for native valve endocarditis, against which antibiotic prophylaxis is given for high-risk dental and surgical procedures. Some species of oral streptococci have been shown to inhibit the colonization of the nasopharynx by other bacteria, and some preliminary studies suggest that the use of these bacteria as bacteriotherapy may reduce the incidence of recurrent otitis media in otitis-prone children.^{4, 5} [***/*]

ANGINOSUS-MILLERI GROUP

Previously *Streptococcus intermedius*, *Streptococcus anginosus* and *Streptococcus constellatus* were separate species, but they are now all included under the genus name *S. anginosus* but are still often referred to as *Streptococcus milleri* in clinical diagnostic laboratories because of their specific disease associations. They are part of the normal nasopharyngeal flora, but can produce invasive disease and are one of the commonest causative isolates found in deep pyogenic lesions, liver, lung and brain abscesses.¹⁸ [**]

ENTEROCOCCI

The enterococci look like streptococci on microscopy but group with group D antisera, are bile tolerant and inherently resistant to a number of antibiotics including the cephalosporins and fluoroquinolones. Outbreaks due to vancomycin-resistant enterococci are increasing in incidence in high-risk areas, such as haematology and renal units. They are part of the normal faecal flora and owing to the antibiotic resistance will often colonize open wounds and the nasopharyngeal flora when a patient is on antibiotics. They are a cause of urinary tract infections, line and implant infections and intraabdominal sepsis.

Corynebacteria species including *Corynebacterium diphtheriae*

Corynebacteria are Gram-positive pleomorphic bacilli with a Chinese lettering-like appearance on Gram stain. Generally, *Corynebacteria* sp. do not produce disease but constitute a major component of the bacterial flora of the human skin and mucous membranes. Only a few species produce human disease in addition to the notable pathogen of this genus *Corynebacterium diphtheriae*, which produces disease by production of the exotoxin

diphtheria toxin that is only produced by strains which have become infected with a lysogenic bacteriophage carrying a specific 'tox gene'. Nontoxigenic strains rarely cause more than local self-limiting disease but lysogenic conversion can occur at a site of colonization, and this has been suspected to have happened in several outbreaks; treatment with a macrolide to eradicate the organism is therefore advised.^{19,20} [**] The diphtheria toxin exerts a lethal effect on all human cells by inhibition of protein synthesis with resulting pharyngeal damage and with absorption into the bloodstream, subsequent myocardial and neurological toxicity. Three biotypes of *C. diphtheriae* exist: *gravis*, *mitis* and *intermedius* types; the *gravis* and *intermedius* types are associated with a higher rate of mortality which is probably related to the amount of toxin production (Figure 16.4). Less commonly *Corynebacterium ulcerans* can also be infected by this bacteriophage and produce a diphtheria-like presentation.²¹ [**]

GRAM-NEGATIVE BACTERIA

Neisseria species

There are ten different members of this genus, of which *Neisseria meningitidis* and *Neisseria gonorrhoeae* are the important pathogens of man. The other species, which include *Neisseria lactamica* and *Neisseria sicca*, are part of the normal upper respiratory tract microflora. These are Gram-negative cocci, which appear in pairs or diplococci in clinical specimens. Gonococci and meningococci have become adapted to survival in man; they therefore require CO₂, 37°C and enriched media for isolation within the laboratory. They are identified on the basis of their biochemical reactions and using monoclonal antisera.

Figure 16.4 *Corynebacterium diphtheriae* var *gravis* on tellurite-containing media showing a typical 'daisy head'-like appearance.

NEISSERIA GONORRHOEAE (GONOCOCCUS)

Gonococci classically produce disease of the genital tract with cervicitis, urethritis and pelvic inflammatory disease. They are also occasionally responsible for sexually acquired pharyngitis and can be carried in the nasopharynx asymptomatically.

NEISSERIA MENINGITIDIS (MENINGOCOCCUS)

Meningococci are further separated with antisera into serogroups A, B, C, W135 and Y. Meningococci can be found as part of the commensal nasopharyngeal microflora in up to 10 percent of the population with higher carriage rates found in institutions and during outbreaks. Investigations of the carriage of meningococci in university students have identified that carriage is a dynamic process with acquisition or loss of strains over time.²² [***] Invasive disease occurs in only a small percentage of carriers with severe disease such as meningitis, meningococcal septicaemia, and rarely, septic arthritis. Currently, in the UK, the main serogroups responsible for invasive disease are B and C. Since 1999 a conjugate serogroup C meningococcal vaccine has been introduced for young teenagers and children, with a dramatic reduction in invasive serogroup C disease.

Moraxella catarrhalis

This organism is morphologically similar to *Neisseria* and thought to be a harmless commensal of the upper respiratory tract. It is now recognized as a cause of infective exacerbations of chronic obstructive pulmonary disease, the third commonest cause of otitis media and a cause of acute sinusitis.²³ [**] They are inherently resistant to penicillins including ampicillin by the production of β-lactamase.

Haemophilus species

Haemophili are Gram-negative pleomorphic coccobacilli and form a major part of the normal respiratory microflora. They have varying requirements for specific growth factors (X) haemin and (V) nicotinamide adenine dinucleotide and will not grow on laboratory media without these nutrients. *Haemophilus influenzae* is the important pathogen of this genus; the other species rarely cause disease and are commonly found as part of the normal nasopharyngeal flora, for example *Haemophilus parainfluenzae*.

HAEMOPHILUS INFLUENZAE

Haemophilus influenzae is identified by its poor growth on blood agar owing to its need for X and V factors, and

contributes about 10 percent of the nasopharyngeal microflora, the majority of which are noncapsulated strains that are one of the commonest causes of otitis media and sinusitis.^{23, 24, 25} [**/*] Both capsulated and noncapsulated strains exist, capsulated being associated with pathogenicity. Capsulated strains can be separated further using antisera against capsular types a–f; the presence of capsular type b is associated with severe invasive disease, most notably meningitis, septic arthritis and epiglottitis. The introduction of the conjugated *H. influenzae* type b (Hib) capsular polysaccharide vaccine in the autumn of 1992 in the UK has been associated with a dramatic reduction in the incidence of Hib invasive disease, both in vaccinated children and nonvaccinated individuals, with the almost disappearance of epiglottitis in children. A slight rise in the incidence of invasive disease has been noted since 1999; clinical recognition and microbiological investigation of this disease is therefore still important.²⁶ [**]

Bordetella pertussis

Bordetella pertussis is the causative organism of pertussis (whooping cough), a small Gram-negative coccobacillus which is fastidious in its growth requirements, requiring up to five days incubation on charcoal-containing media. Virulence factors that contribute to disease include filamentous haemagglutinin, a cell-surface associated adherence protein that mediates bacterial host–cell interaction and pertussis toxin, which mediates the paroxysmal cough and induces lymphocytes producing the characteristic lymphocytosis. Disease is most commonly seen in infants too young to have been vaccinated and in families who have declined immunization. The reservoir of infection is adult carriers and subclinical cases, as immunity from the vaccine wanes after childhood.

Enterobacteriaceae (aerobic Gram-negative bacilli)

There are over 100 different species in this family, which are normally found as part of the bowel microflora and are able to grow under aerobic and anaerobic conditions and in the presence of bile salts. They are not normally found in the nasopharynx of fit individuals in the community, but become part of the nasopharyngeal flora in sick, hospitalized patients, such as ventilated patients on intensive care units, from where they can produce lower respiratory tract infection. They are separated in the clinical laboratory on the basis of simple biochemical reactions such as fermentation of sugars. Only a few of the genera and species commonly produce disease, for example *Escherichia coli*, *Klebsiella* sp. They are the isolates commonly found from cases of urinary and

abdominal sepsis, but rarely produce infection in the upper respiratory tract in the UK. *Klebsiella rhinoscleromatis* is a Gram-negative organism that can produce chronic granulomatous infection of the upper respiratory tract, rarely found in the UK but is endemic in some parts of South America, Asia and Eastern Europe.

***Pseudomonas* species**

These are environmental unreactive thin Gram-negative bacilli, which are inherently resistant to most antimicrobials and disinfectants, and survive well in moist warm environments. They cause opportunistic infection, when the host normal barrier to infection is compromised by disease, for example skin damage by burns.

Pseudomonas aeruginosa is the commonest pseudomonad to produce opportunistic infections. It is recognized in culture and sometimes in clinical samples by its ability to produce pigments or pyocyanins. It is commonly found colonizing breaks in the skin, such as leg ulcers and surgical wounds, particularly when the patient has been on antibiotics. In chronic otitis externa *P. aeruginosa* is often found to colonize the damaged ear canal. Invasive disease and infection is rare but is occasionally seen in immunosuppressed and poorly controlled diabetic patients.^{27, 28}

ANAEROBES AND MICROAEROPHILIC BACTERIA

Anaerobes

There are a number of both Gram-positive and -negative organisms which only survive in strict anaerobic conditions, i.e. in the complete absence of oxygen. They make up a large part of the normal oral and large bowel microflora, and only a few of the anaerobic genera found in man commonly produce infection. The restricted activity of metronidazole against anaerobes is used in the diagnostic laboratory to help detect the presence in polymicrobial mixtures of the relatively slower growing anaerobes. Anaerobes are more likely to be isolated from clinical samples if a large volume of the pus rather than a swab is sent quickly to the laboratory and strict anaerobic conditions with prolonged incubation are maintained in the laboratory.

Bacteroides fragilis is a Gram-negative bacillus found in small numbers in the oral and large bowel microflora but is the commonest anaerobe found in infections, which are usually polymicrobial with a synergistic mixture of aerobic and anaerobic bacteria. The characteristically fusiform Gram-negative bacillus *Fusobacterium necrophorum*, which is part of the normal oral flora, occasionally produces the rapidly progressive invasive

disease 'necrobacillosis' without the need for the presence of other bacteria.²⁹ [**]

Microaerophilic bacteria, for example *Actinomyces*

Unlike anaerobic bacteria, some organisms are able to tolerate microaerophilic conditions with very low concentrations of oxygen, for example *Actinomyces* sp. *Actinomyces* are usually found as part of the normal oral and large bowel microflora. If there is trauma or injury they can penetrate deep tissues and produce disease, which is often polymicrobial in nature and known as actinomycosis. Characteristically clumps of Gram-positive bacilli can be seen on histology or Gram staining but also sometimes in the sample of pus, producing sulphur-like granules. *Actinomyces israelii*, *Actinomyces meyeri* and *Actinomyces odontolyticus* are the species which are usually isolated from clinical samples. They are difficult to isolate as they are slow growing, often mixed with other organisms and require microaerophilic conditions; they are generally sensitive to penicillin.

OTHER BACTERIA

Mycobacteria

Mycobacteria are acid- and alcohol-fast bacilli that usually grow slowly in aerobic conditions and are not isolated on routine agar media. There are 25 *Mycobacterium* sp., which are usually split into *Mycobacterium tuberculosis* and the 'atypical' mycobacteria.

MYCOBACTERIUM TUBERCULOSIS (INCLUDES MYCOBACTERIUM BOVIS)

It characteristically grows slowly on agar containing fatty acids, such as the egg-containing Löwenstein-Jensen media, taking four to six weeks for visible colonies to appear, so it cannot be isolated by conventional culture (Figure 16.5). It is looked for in clinical samples using the Ziehl-Nielsen stain or a modification of this using auramine, exploiting the acid- and alcohol-fast characteristics of the mycobacterial cell wall. In the laboratory, samples and cultures for tuberculosis have to be handled in a category 3 laboratory using a safety cabinet to minimize the risk of laboratory-acquired infections. On being sent to the clinical laboratory, specimens that may contain *M. tuberculosis* must therefore be labelled as such, so that they can be handled safely, but also so that specific stains and cultures are performed which will not be routinely carried out. The use of liquid culture media with automated detection of growth and DNA probes to identify any acid-fast bacilli isolated can decrease the isolation time of these organisms.

© Hodder Arnold / Scott-Brown 7E

Figure 16.5 *Mycobacterium tuberculosis* on Löwenstein-Jensen media demonstrating the characteristic buff-coloured breadcrumb-like appearance.

'ATYPICAL' MYCOBACTERIA

This includes *Mycobacterium avium intracellulare*, *Mycobacterium kansasii*, *Mycobacterium scrofulaceum* and *Mycobacterium mageritense* which are responsible for cervical adenitis in children under 12 years of age.^{30, 31} [**] They vary in their colonial appearance and time to positive culture and sensitivity to antimicrobials from *M. tuberculosis*. Disseminated *M. avium intracellulare* infection can be a late opportunistic infection in HIV patients.

Mycoplasmas

Mycoplasmas do not have a cell wall and are therefore difficult to isolate on routine culture media, thus diagnosis is therefore based on serological tests. *Mycoplasma orale* and *Mycoplasma salivarium* are part of the normal nasopharyngeal flora but do not produce disease. *Mycoplasma pneumoniae* is the important pathogen of this group, as it is a common cause of pneumonia in children and young adults with epidemics every four years, but it is probably a rare cause of otitis media. Owing to the lack of a cell wall, antibiotics which target cell wall synthesis are inactive against mycoplasmas; the macrolides, tetracyclines and fluoroquinolones are effective.

Chlamydiae

These are tiny Gram-negative intracellular bacteria, which form inclusion bodies in the cytoplasm of infected cells. They lack some of the enzymes required for independent existence and must replicate intracellularly. There are three main species which produce disease in humans:

1. *Chlamydomonas psittaci*: severe lower respiratory tract infection, infections in birds;
2. *Chlamydomonas trachomatis*: ocular, genital and occasionally respiratory tract infection;

3. *Chlamydomphila pneumoniae*: upper and lower respiratory tract infection.

In the mid-1980s it was recognized that *C. psittaci* actually contained two differing species: *C. pneumoniae* which generally produces less severe disease only in humans and *C. psittaci* which produces more severe systemic disease and pneumonia.³² [**/*]

Laboratory diagnosis of chlamydial infections is difficult as they require cell culture to be isolated, so it is usually based on finding rising titres of complement-fixing antibodies to whole cell antigen preparations (except genital *C. trachomatis* infections). There is cross reaction between the antibodies to the different species. Species-specific antibodies can be detected by microimmunofluorescence techniques. Detection of species-specific DNA using polymerase chain reaction has been used in studies of upper respiratory tract infections but not routinely.

Cell wall active antimicrobials are inactive and treatment is usually with macrolides, tetracyclines and the newer fluoroquinolone antibiotics.

Spirochaetes

These are irregular curved motile bacteria which have a characteristic appearance on microscopy but are not isolated on routine culture.

Borrelia species

Borrelia vincentii is the organism found in acute necrotizing gingivitis and Vincent's angina, accompanied by anaerobic fusobacteria organisms. *Borrelia burgdorferi* is the causative organism of Lyme disease.

Treponema pallidum

This is the causative organism of syphilis in the primary or secondary stages and can be seen in dark ground microscopy of lesions, but it cannot be isolated on artificial media. Diagnosis is based on a combination of serological tests. The syphilis enzyme immunoassay has replaced the traditional cardiolipin antibody tests (e.g. Venereal Disease Research Laboratory (VDRL)) as a screening test, as the VDRL was troubled by biological false positives. Specific treponemal tests, for example TPHA and TPPA are positive later in the course of an infection but remain positive for life and are positive after other treponemal infections, for example yaws. Syphilis has recently re-emerged as a public health problem in the UK with outbreaks of primary and secondary infections occurring in individuals with high-risk sexual behaviour. This disease therefore needs to be considered as a cause of painless mucosal or cutaneous lesions.

KEY POINTS

- The nasopharynx has resident commensal bacteria which can include pathogens.
- There is some evidence to suggest that the commensal bacterial flora protects against invasive disease.
- Nearly all bacteria are separated on the basis of the Gram stain, growth characteristics and biochemical reactions.
- New pathogens have recently been identified, e.g. *C. pneumoniae*, while others await identification and old diseases and pathogens are re-emerging, e.g. syphilis.

Viruses and antiviral agents

PAUL SIMONS AND KARL G NICHOLSON

Introduction	204	Key points	211
Respiratory tract viral infections	204	Best clinical practice	211
Herpes viruses	207	Deficiencies in current knowledge and areas for future research	211
Viruses and malignancy	208	References	211
Antivirals	209		
Conditions with a viral aetiology	210		

SEARCH STRATEGY

Medline searches were undertaken for conditions with viral aetiology. For example, for the viral aetiology of sensorineural hearing loss, the key words used were sensorineural hearing loss and virus. Searches were also undertaken using specific viruses as key words, for example influenza and mumps, in conjunction with serology.

INTRODUCTION

Viruses frequently infect the ear, nose and throat. As well as causing local symptoms and complications they can also be involved in the pathogenesis of malignancy. This chapter covers viruses that primarily infect the respiratory tract; others, such as hepatitis B and C, are not dealt with here but are of relevance to all surgical specialties. Human immunodeficiency virus (HIV) is covered in a dedicated chapter (Chapter 20, HIV and otolaryngology) and not discussed here.

RESPIRATORY TRACT VIRAL INFECTIONS

Respiratory tract viral infections are the commonest diseases affecting humans worldwide, and account for 30 percent of all childhood deaths in the developing world.¹ Most preschool children experience six to eight viral respiratory infections per year; episodes in adults are responsible for a significant number of lost working days. The respiratory tract is one of the commonest sites for viral infection, partly due to its accessibility and large surface area.

Annual illness rates are almost 85 percent with one-third requiring medical attention. Many viruses have characteristic seasonal activity. For example, parainfluenza types 1 and 2 outbreaks happen predominantly in autumn, type 3 in spring and respiratory syncytial virus (RSV) outbreaks during winter.

Pathogenesis

Respiratory viruses infect cells by binding host-cell receptors. Most rhinoviruses, for example, bind the intercellular adhesion molecule receptor (ICAM-1). In influenza the resulting interferon response is likely to account for the majority of systemic symptoms, and mediators such as bradykinins are largely responsible for local symptoms.

Diagnosis

Viral pathogens are diagnosed by a variety of techniques. Inoculation of respiratory secretions on to tissue culture has traditionally been the mainstay of diagnosis. Enzyme

Table 17.1 Viruses causing respiratory illness.

Illness	Virus
Pharyngitis	PIV/CMV/adenovirus/influenza A and B/HSV/Coxsackie/enterovirus
Pneumonia/pneumonitis	RSV/parainfluenza type 3/rhinovirus/coronavirus
Common cold	Rhinovirus/coronavirus/parainfluenza type 4
Croup	Parainfluenza types 1, 2 and 3/RSV/influenza
Bronchiolitis	RSV/parainfluenza type 3/influenza
Flu'	Influenza A and B
Bronchitis	PIV/RSV

immunoassay and immunofluorescent-labelled antibody against viral antigens allow more rapid detection. Viral nucleic acid can be detected by polymerase chain reaction (PCR) giving greater sensitivity and not necessitating live virus to be present. Nasopharyngeal aspirates are the preferred specimen as nose and throat swabs produce a lower yield. Serology is widely used, and although some viruses are detected by specific immunoglobulin (Ig)M antibody tests, diagnosis based on convalescent IgG rise is retrospective and entails delay. Viruses causing respiratory illness are shown in **Table 17.1**.

Coronavirus

Coronavirus is the largest human RNA virus and is transmitted predominantly by aerosol spread. There are two human strains (229E and OC4) that infect epithelium of the trachea, nasal mucosa and alveolar cells of the lung. Coronavirus causes up to 10 percent of cases of 'common cold', particularly in the winter. Infection causes nasal discharge, malaise and exacerbations of airways disease; cervical lymphadenitis, cough and fever are less common.

Adenovirus

Adenovirus is a double-stranded DNA virus originally isolated from human adenoid tissue; over 45 serotypes exist. Most children are asymptotically infected with types 1 and 2 in early childhood and types 3 and 5 predominate in later life. Transmission is by aerosol and probably faecal and oral spread.

Adenovirus causes outbreaks of upper and lower tract illness in institutions and small communities, particularly in winter. Certain types present with specific features, for example type 2 causes mild illness compared with types 3 and 7, which are associated with pneumonia in young children. Pharyngoconjunctival fever often occurs in swimming pool outbreaks involving children and young adults, and epidemics of keratoconjunctivitis are associated with inadequately sterilized instruments. Adenovirus causes a variety of respiratory tract syndromes including exudative tonsillitis with a high fever, pharyngitis and pneumonia, and type 7 may cause disseminated disease.

Animal models suggest that the virus directly infects bronchiolar epithelium with most local damage being due to the immune responses rather than the virus itself. There are case reports of success using ribavirin in treating childhood adenoviral pneumonia.² [**]

Rhinovirus

Rhinovirus is a small, nonenveloped RNA virus with well over a hundred serotypes. Replication is restricted to cells of the upper respiratory tract with optimal growth at lower temperatures of about 33°C. Transmission is by aerosol and contact with contaminated surfaces, such as hands and utensils. Symptoms are partly due to bradykinin release and include nasal congestion, sneezing, sore throat, headache and cough. Infection occurs throughout the year with several serotypes in circulation which results in people succumbing to repeated infection. Although symptoms are usually minor they can cause a significant amount of time off work, and important complications, such as exacerbation of airways disease. Infection with one serotype does not result in immunity to another and vaccination is not practical owing to the large number of serotypes. Antiviral agents such as enviroxime and dichloroflavan have shown no therapeutic benefit in randomized double-blind controlled trials.^{3,4} Controlled trials of vitamin C have also shown no definite benefit.⁵ [****]

Influenza

Influenza is an RNA orthomyxovirus with subtypes A, B and C (**Figures 17.1, 17.2 and 17.3**). Transmission occurs by droplet spread and the incubation period is one to three days. Outbreaks often begin suddenly, peaking within four weeks and usually last between eight and ten weeks. In the UK there are up to 25,000 deaths per year, mainly in older people and those with chronic illness. Pandemics of influenza are unpredictable and during the last century occurred at intervals of 11–39 years; the pandemic of 1918 killed 20–40 million people.

Typical symptoms include fever, chills, headache, myalgia, anorexia and malaise. Although a primary viral

Figure 17.1 Diagram of influenza virus. H, haemagglutinin; M, matrix protein; N, neuraminidase; NP, nucleoprotein; RNA, ribonucleic acid.

Figure 17.2 Influenza virus detected by immunofluorescence. Courtesy of Dr Zambon, HPA.

pneumonia may occur, pneumonia is often due to secondary *Staphylococcus aureus* superinfection. Other less common complications include myocarditis and pericarditis. In susceptible people infections may cause exacerbations of chronic obstructive pulmonary disease (COPD), asthma and heart failure. In children, complications include otitis media, croup, bronchiolitis and febrile convulsions. Ciliated columnar cells are primarily infected with necrosis and impairment of the mucociliary escalator which predisposes to bacterial infection. Annual immunization is recommended each autumn for those considered at greatest risk of serious complications including the elderly, diabetics, patients with chronic liver, cardiac, respiratory and renal disease, the immunosuppressed and those in long-stay care. Comparatively

Figure 17.3 Electron micrograph of influenza virus. Courtesy of Dr Appleton, HPA.

little is known about the epidemiology and burden of influenza C which typically causes sporadic infections with common cold symptoms or is subclinical. Sporadic infections are the rule. Avian H5N1 influenza is particularly virulent and has the capacity to infect humans resulting in significant mortality. It originates from wild and domestic birds in South East Asia and has recently spread into Europe.

Mumps

Mumps is a highly infectious RNA virus with an incubation period of two to three weeks. Infection is transmitted to the respiratory tract by droplet transmission and close contact.

Fever and malaise occur at the onset and parotid enlargement develops within one to two days. Swelling usually subsides over a few days but may cause transient facial nerve palsy. One in five men develops orchitis (usually if mumps is contracted after puberty) and atrophy occurs in one-third, although sterility is uncommon. Other complications include encephalitis and aseptic meningitis with residual deafness. Serum amylase may be elevated for several weeks after parotitis and pancreatitis. Vaccination with live attenuated vaccine (trivalent mumps–measles–rubella) (MMR) has dramatically reduced cases of infection.

Measles

Measles has an incubation period of 14 days and causes infection in children between three and six years of age, particularly in winter and spring. The virus replicates in the respiratory and conjunctival epithelium, several days later it is found in reticuloendothelial organs. Typical symptoms are rhinorrhoea, cough, fever and 'Koplik's

spots' on mucous membranes of the cheeks. A few days later a maculopapular rash appears, starting on the face, then affecting the trunk and limbs. There may be high fever and other features of the illness include bronchitis, pneumonitis and diarrhoea. Complications include croup, otitis media, conjunctivitis, enteritis, febrile convulsions (and rarely post-exposure encephalitis and subacute sclerosing panencephalitis). Live-attenuated vaccine is given in combination with mumps and rubella. In developing countries over one million children die every year due to insufficient vaccine coverage, younger age of infection and concurrent malnutrition.

Respiratory syncytial virus

Respiratory syncytial virus is an RNA virus with two serotypes A and B. The virus is particularly contagious and causes winter outbreaks in infants and epidemics that last for months. It is sometimes misdiagnosed as influenza in older people and is responsible for approximately one million childhood deaths annually in developing countries. Transmission is through contact with respiratory secretions rather than by aerosol. The incubation period is between two and eight days. Infants from six weeks to six months are predominantly infected and most children have been exposed to the virus by two years of age. Coryzal symptoms occur initially but the illness may progress rapidly to cause respiratory distress within 24 hours, particularly in those with underlying cardiac or pulmonary disease. Significant morbidity and mortality is seen at the extremes of age.

Respiratory syncytial virus causes necrosis of bronchiolar epithelium and lung parenchyma causing bronchiolitis and, less commonly, pneumonitis. Infection is associated with recurrent wheezing but does not necessarily cause asthma in older children. The interferon response is greater than with other paramyxovirus infections resulting in more severe systemic symptoms. Reinfection is frequent and likely to be due to antigenic variation.

As vaccine development has not been successful, preventative measures, such as limiting aerosol spread, cohorting and hand washing, are important.

It is unclear whether the use of ribavirin or steroids reduces morbidity or mortality and their use remains controversial. Ribavirin as a prophylaxis is generally reserved for high-risk infants.⁶

Parainfluenza virus

Parainfluenza virus (PIV) causes nearly a third of all respiratory tract infections. PIV 1 and 2 cause autumn croup outbreaks every one to two years. PIV 3 is endemic and usually causes infantile bronchiolitis and pneumonia. Type 4 is less common and can cause both upper and lower tract infection. Parainfluenza virus infection causes

exacerbations of COPD, asthma and cystic fibrosis. Person to person spread is the main mode of transmission. Detection is by indirect immunofluorescence of antigen and PCR of nasopharyngeal aspirates. Nebulized ribavirin has been used in PIV infection in children with immunodeficiency. Vaccines are currently being evaluated clinically.

HERPES VIRUSES

Herpes simplex virus

Herpes simplex viruses (HSV) are double-stranded DNA viruses. Types 1 and 2 both cause primary infection and reactivation. After entry into the skin, the virus replicates locally forming vesicles of degenerating cells and fluid. HSV then tracks along sensory nerves and remains dormant in sensory ganglia. Reactivation is precipitated by several factors including trauma, stress, menstruation, fever, extremes in temperature and ultraviolet light.^{7,8} Humans are the only known host and transmission is by direct contact with infected mucosal secretions from active lesions or asymptomatic secretors. HSV-1 is mostly contracted from oral and HSV-2 from genitourinary secretions.

During primary oral disease, an incubation period of between two days and two weeks is followed by sore throat, pharyngitis and febrile illness. Painful vesicles may develop on the oropharynx with progression resulting in extensive gingivostomatitis and lesions extending onto the cheeks and lips, persisting for several days (**Figure 17.4**). Other complications include HSV encephalitis, meningitis, erythema multiforme and eczema herpeticum. HSV is implicated in the aetiology of Bell's palsy.

Recurrent infections

Recurrent labial herpes begins with symptoms of itching, burning, tingling and pain lasting between six hours and

Figure 17.4 Herpetic gingivostomatitis.

two days. Lesions often occur on the lips and perioral skin and may extend into the nostrils. Multiple recurrences are usually at the same site, some become secondarily infected with *Staphylococcus aureus*. Complete healing may take up to two weeks. Of those infected with latent virus, less than 10 percent have one attack per month and 50 percent have approximately two attacks per year.⁹

Although the diagnosis is usually clinical, the virus can be isolated and detected by electron microscopy, antibody tests and tissue culture.

Treatment

Although topical preparations are used for labial herpes, systemic treatment is required for severe or recurrent episodes. Famciclovir and valacyclovir are generally used in preference to acyclovir as they have better oral absorption. Although drugs reduce the severity and duration of symptoms, they do not eradicate the virus. Antivirals should be used immediately symptoms arise and preferably before any vesicles develop. Other approaches include preventative intermittent therapy where treatment is taken before exposure to the trigger factor. Using this approach, recurrence has been reduced by 80 percent using famciclovir¹⁰ and by 50–78 percent with acyclovir.¹¹ Patients who experience more than 6–12 episodes per year should be considered for long-term prophylaxis with the minimum dose to prevent recurrence.¹² It should be noted that data are extrapolated from the outcome of genitourinary tract lesions. [****]

Treatment of recurrent infection in the immunocompetent host is often unnecessary unless symptoms include neuralgia and systemic upset. In immunocompromised patients, however, recurrences may be prolonged and severe. Long-term therapy may be required and carries the risk of drug resistance. Prevention is difficult as many carriers are asymptomatic; gloves should be used if contact is likely.

A number of HSV vaccines are under investigation. It is hoped that as well as preventing primary HSV infection, increased immunity will reduce the severity and frequency of recurrent episodes.⁹

Epstein-Barr virus

Epstein-Barr virus (EBV) is a DNA virus that infects B lymphocytes and epithelial cells of both oral and genital tracts. Primary infection is often subclinical resulting in asymptomatic lifelong carriage. Infectious mononucleosis arises in approximately half of young adults who are not infected during childhood. Symptoms include sore throat, fever and disproportionate fatigue. There may be transient periorbital oedema and a characteristic maculopapular rash is typical in those taking ampicillin. Dysphagia occurs with tonsillar and pharyngeal oedema

in 50 percent, sometimes with greyish exudates. Generalized lymphadenopathy and hepatosplenomegaly usually resolve within one to two weeks. A minority of patients have protracted lethargy and lymphadenopathy. The infection appears to initiate the onset of recurrent bacterial tonsillitis in a proportion of patients. These patients often fail to resolve with time and some require tonsillectomy. Rarely, the degree of tonsillar hypertrophy is so marked that the upper airway can become obstructed. The use of parenteral steroids helps tonsillar swelling to resolve, avoiding the need for tracheostomy. Complications include airway obstruction, splenic rupture, secondary bacterial pharyngitis, haematological problems and Guillain-Barré syndrome. Malignant disease associated with EBV is discussed below.

VIRUSES AND MALIGNANCY

Several human viruses are associated with malignancy by interfering with cell proliferation and growth. Insertion of viral oncogenes or integration of viral DNA into a region which disrupts a tumour suppressor gene can confer malignant properties to the host cell. Human papilloma virus (HPV) may cause carcinoma of the skin, genitalia and larynx. 'High-risk' genotypes 16 and 18 cause malignancy owing to the ability of E6 and E7 protein to bind to cell-suppressor proteins Rb and p53.¹³

Epstein-Barr virus

Epstein-Barr virus causes a number of malignant diseases including nasopharyngeal carcinoma, Burkitt's lymphoma (BL) and B-cell lymphoma. BL is a B-cell tumour typically involving the mandibular area and occurs in children aged 4–12 years. Malaria is considered a cofactor as BL is endemic in certain areas of Africa where malaria is hyperendemic. EBV can be detected in 95 percent of tumours, the malignancy is thought to be due to translocation of immunoglobulin genes to the region of the c-myc oncogene which then becomes deregulated.¹³ Cyclophosphamide is the treatment of choice, often giving good results.

Nasopharyngeal carcinoma has a high incidence in south China, Indonesia, Vietnam and those with an A2BW36 haplotype. It arises primarily in the post-nasal space from squamous epithelial cells. EBV is widely accepted as a cofactor along with racial predisposition.

Epstein-Barr virus is present in malignant cells and serum antibody titres correlate with tumour burden, although the mechanism of oncogenesis is unclear.

Hairy oral leukoplakia is considered a premalignant condition consisting of painless, white, raised lesions on the lateral aspect of the tongue. The condition occurs in HIV infection and other causes of immunosuppression. Squamous epithelial cells have been demonstrated to

Table 17.2 Associations of pathology and HPV type.

Condition	HPV type	Less common
Oral papilloma	Various	
Heck's tumour	13, 32	
Multiple papillomatosis	6, 11	67
Laryngeal papillomatosis	16, 11	6
Laryngeal carcinoma	16, 18	6, 11, 30
Inverted papilloma	6, 11	18

contain large amounts of actively replicating EBV. Acyclovir inhibits EBV replication but only to an extent to allow transient lesion regression.

Lymphomas occur more commonly in immunocompromised and HIV-infected individuals. In Hodgkin's and oral T-cell lymphoma, EBV DNA is expressed by tumour cells. Persistent EBV infection becomes uncontrolled in the immunosuppressed and there is an increase in viral replication and the numbers of virus-carrying B lymphocytes. Although this condition can remain 'silent', loss of immune control can lead to EBV-associated lymphomas.¹⁴

Human papilloma virus

Human papilloma virus is a double-stranded DNA papovavirus with a predilection for human epithelial cells. Of the 60 types that exist, perinatal acquisition of types 6 and 11 from an infected maternal genital tract may result in juvenile-onset recurrent respiratory papillomatosis. Respiratory papillomas are the most common laryngeal tumour and occur in young adults and the under 5 age group. They are usually single and pedunculated and rarely recur after excision. Although rare, the condition may be life-threatening if airway obstruction develops. The vocal cords are most commonly affected, resulting in hoarseness and dysphonia. Infection with types 13 and 32 appear to be confined to the mouth, types 6 and 11 may rarely progress to cause invasive cancer. Although Caesarean section is effective in reducing transmission, it is not routinely practised owing to the large number needed to avoid one case of infection. Trials of HPV vaccination are currently being evaluated.

ASSOCIATIONS OF PATHOLOGY AND HUMAN PAPILLOMA VIRUS TYPE

Associations of pathology and HPV type are presented in Table 17.2.

ANTIVIRALS

Vaccination has been highly effective in controlling certain viral diseases such as measles but is ineffective

against others, such as those with multiple serotypes, for example rhinovirus. Of the antiviral agents that have been developed some theoretically have a broad range of activity, such as interferon, other drugs, such as aciclovir, are more virus specific.

Antiviral agents **target specific points** of the virus replication cycle. Virus **uncoating** is inhibited by amantadine with activity against influenza A. Herpes DNA **polymerase** is inhibited by acyclovir and foscarnet; inosine-5-monophosphate dehydrogenase is inhibited by ribavirin. **Virus release** is blocked by the influenza neuraminidase inhibitors, zanamivir and oseltamivir.

Interferon

Interferons (IFN) are naturally occurring substances with antiviral properties. Virus-infected cells release soluble factors in response to viral infection. Surrounding cells release ribonuclease, 2–5A synthetase and protein kinase which together degrade RNA and inhibit viral protein synthesis. Interferon as a therapeutic agent is less effective *in vivo* than hoped. Unpleasant adverse effects such as 'flu-like' symptoms and haematological complications limit its use. Alpha interferon is used with success, however, in chronic hepatitis B and C infection, often in conjunction with lamivudine and ribavirin, respectively.

Acyclovir

Acyclovir, a pro-drug, is phosphorylated by the thymidine kinase of the herpes virus. The active monophosphate inhibits herpes DNA replication. Acyclovir is used in the treatment of HSV and herpes zoster (HZV) infections and given as prolonged courses in those with recurrent HSV-1 and -2 infections. It is used as prophylaxis in bone marrow and organ transplant patients. High doses are given for varicella zoster virus (VZV) or HSV in the immunocompromised and HSV encephalitis.

Ganciclovir is a related compound with more activity against cytomegalovirus (CMV) than acyclovir. It is also more toxic and usually reserved to treat conditions such as CMV oesophagitis and retinitis in the immunocompromised.

Influenza neuraminidase inhibitors

Zanamivir is an influenza A and B neuraminidase inhibitor administered by powder inhalation. Administration is recommended within 48 hours of symptoms. Although it does not appear to reduce serious complications or mortality, it shortens illness duration by approximately one day. There is insufficient evidence as to whether it affects hospitalization rates and is intended

currently for 'at risk adults' only.¹⁵ Oseltamivir is similarly effective and is safe and well tolerated.

Other antivirals used against influenza include amantadine and rimantidine. These block membrane ion channels and inhibit induction of RNA synthesis. Although rimantidine is used in the USA and Canada, it is not available in the UK and most other European countries. Amantadine is effective against influenza A only, it is poorly tolerated and is associated with a high incidence of drug resistance.

Ribavirin

Ribavirin is a synthetic analogue of guanosine. *In vitro* it has good activity against a range of viruses including RSV, measles, influenza A and B, hepatitis A, B and C as well as HIV. However, *in vivo* it has dose-limiting toxic effects and few clinical indications. It is used in hepatitis C infection and is administered by aerosol inhalation in pediatric cases of severe RSV infection. Its efficacy is controversial with many studies failing to show significant benefit.¹⁶ Ribavirin has activity against influenza A and B *in vitro*, but is not licensed or used clinically as no real efficacy has been demonstrated in humans.

CONDITIONS WITH A VIRAL AETIOLOGY

Bell's palsy

Bell's palsy is an acute, idiopathic, lower motor neurone unilateral facial paralysis. The incidence is approximately 20 per 100,000 per year and increases with age. There is equal sex predominance. The lifetime incidence is 1 in 60–70 with a peak between ages 10 and 40.¹⁷ The course is usually benign but significant sequelae are seen in 16 percent of those affected.¹⁸ Although the cause is unclear a number of aetiologies has been suspected, including viral infection, vascular ischaemia and autoimmune dysfunction. The viral reactivation theory became popular after detection of the HSV-1 genome in endoneurial fluid in patients with Bell's palsy. The viral theory is widely¹⁹ but not universally accepted.¹⁷

Treatment

There have been studies comparing the efficacy of steroids, acyclovir and facial nerve decompression. In a review of studies there were no adequately powered class 1 studies, and no significant difference in outcome using steroids. One randomized control trial with limitations demonstrated decreased frequency of motor synkinesis with steroids.²⁰ Two randomized control trials showed an increased proportion of those with good recovery of

motor function in the group who received acyclovir and prednisolone compared with using prednisolone alone. There was no difference in incidence of longer-term sequelae, and authors have encouraged results to be interpreted with caution.²¹ [****]

Santos-Lasaosa *et al.* have stated that 'in spite of recent trials' the generally accepted treatment is prednisolone (1 mg/kg per day).¹⁸ Further well-designed studies of treatment efficacy are still needed.²⁰

In view of the above it should be noted that HSV and VZV viruses are ubiquitous in the population and often found in cranial nerve ganglia of unaffected as well as affected individuals. A significant difference has yet to be demonstrated before an aetiological role can be attributed to the virus.²²

Other conditions, such as postoperative trigeminal sensory deficit, have been attributed to viral reactivation and prompted interest in prophylactic acyclovir.²³

Inverted nasal papilloma

Human papilloma virus has been implicated in the aetiology of inverted sinonasal papilloma using PCR techniques.^{24, 25} It may also cause malignant transformation and is possibly associated with disease recurrence.²⁶ The prevalence of HPV in samples using PCR varies from between 11 percent²⁷ and almost 80 percent;²⁵ type 11 is most commonly detected.^{24, 26, 27}

Opinion is divided whether histopathological dysplasia predicts the prognosis of lesions and there is considerable interest as those with a benign or malignant clinical course have been shown to be separable on the basis of HPV type.²⁴ HPV types 6 and 11 are associated with benign lesions and HPV-18 with malignant lesions. Other studies (with lower HPV detection) dispute whether screening for HPV is a useful prognostic parameter.²⁷ [****/***]

Sensorineural hearing loss

Many viruses, even the common cold, are capable of producing sensory neural hearing loss (SNHL).²⁸ Specific viruses implicated in acute hearing loss include, rubella, mumps, measles, herpes zoster, CMV and influenza.

In a study of 77 cases of idiopathic sensory hearing loss, 65 percent of cases had serological evidence of viral infection as follows: influenza A in 8, influenza B 18, rubella 16, HSV 8, mumps 8 and rubella 7 percent. Almost 50 percent of samples showed evidence of multiple infectious agents.²⁹

Mumps and 'silent mumps' are considered causative factors of 'idiopathic sudden sensory neural hearing loss' with serological evidence of infection of approximately 7 percent.³⁰

A number of respiratory viruses have been linked to the postviral olfactory disorder. Although RSV, herpes and influenza have been implicated, parainfluenza 3 is the most likely causative virus based on serology.³¹

Live attenuated virus vaccines have also been implicated in SNHL. Cases of otherwise unexplained SNHL have been reported following MMR vaccination.³² [****/**]

Viral acute otitis media

Viruses causing upper respiratory tract infection are important in the aetiology of acute otitis media (AOM). Rhinovirus and RSV are most commonly detected; adenovirus, coronavirus and PIV are found less frequently.³³ Recent data indicate that some viruses actively invade the middle ear. There is optimism that vaccination may be effective in preventing virally mediated AOM.³⁴ It has been shown that influenza vaccination is 30–36 percent effective against the development of AOM.³⁵ As viral and bacterial infection often coexist antimicrobials are still advised,³³ although a poor clinical response is often seen in children.³⁴

KEY POINTS

- Respiratory viruses are very common and cause significant morbidity and mortality.
- A variety of viruses cause respiratory illness; RSV can cause a rapid deterioration in children.
- EBV and HPV are associated with a variety of malignant and premalignant conditions in the head and neck.
- Vaccination is highly effective in certain viral diseases. In others the characteristics of the virus have prevented effective vaccine development.
- Some antivirals, such as acyclovir, are highly effective while others have a limited role in controlling illness.
- In recurrent herpes infection, acyclovir and famciclovir are effective in reducing episodes by up to 80 percent.

Best clinical practice

- ✓ Influenza immunization is recommended for at risk groups including those over 65, patients with chronic liver, cardiac, respiratory and renal disease, diabetes, immunosuppression and those in institutions.

- ✓ Although acyclovir is not always necessary in the immunocompetent patient it is recommended in the immunocompromised, and at high dose in serious infection.
- ✓ In recurrent herpes simplex famciclovir or valacyclovir should be taken immediately symptoms begin.

Deficiencies in current knowledge and areas for future research

- Further quality studies of steroids and antivirals are needed in the management of Bell's palsy.
- Vaccine development for respiratory viruses, including RSV and PIV.
- Development of further effective antivirals against influenza and other respiratory viruses.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the following key words: ear, nose, sinus, larynx, throat, *Aspergillus*, *Blastomyces*, *Candida*, *Coccidioides*, *Conidiobolus*, *Cryptococcus*, *Histoplasma*, *Rhinosporidium*, *Zygomycetes*, fungi, aspergillosis, blastomycosis, candidiasis, coccidioidomycosis, cryptococcosis, entomophthoromycosis, histoplasmosis, mucormycosis, otomycosis, rhinosporidiosis, sinusitis and zygomycosis.

INTRODUCTION

With the exception of two conditions, otomycosis and oropharyngeal candidiasis, fungal infections are uncommon in ear, nose and throat practice. There are, however, a number of different mycotic diseases that the otorhinolaryngologist should be aware of as they can mimic other conditions and occasionally have serious consequences if they are not recognized.

MYCOTIC DISEASES OF THE EAR

Otomycosis

DEFINITION

The term otomycosis is used to describe a superficial, diffuse, fungal infection of the ear canal. Otomycosis generally occurs unilaterally among healthy individuals; however, a predisposing condition is usually present.

AETIOLOGICAL AGENTS

Otomycosis is most commonly caused by *Aspergillus* species, particularly *A. niger*, *A. flavus*, and *A. fumigatus*, and *Candida* species, particularly *C. albicans*, *C. parapsilosis* and *C. tropicalis*.^{1, 2, 3, 4} Studies conducted in temperate regions showed a slight preponderance of *Candida* species while those conducted in tropical and subtropical regions found *A. niger* to be the commonest cause of infection.^{1, 2, 3, 4} Other moulds that have been implicated include *Penicillium* species and *Rhizopus* species. Mixed bacterial and fungal cultures are common and account for more than 50 percent of all cultures in otomycosis.¹ [**]

EPIDEMIOLOGY

The aetiological agents of otomycosis are commonly found in indoor and outdoor air, in the soil and dust, and on decomposing plant matter. Their prevalence varies with climatic conditions, but warm humid environments support their growth and the human ear canal is ideal for

their proliferation. In tropical countries, otomycosis has been reported to account for 6 percent of patients with symptoms of ear disease,² but the disease is less common in temperate climates. Otomycosis occurs in adults of all ages and of both sexes, but children are less commonly affected.^{1, 2, 3} It is not contagious. Otomycosis often develops in individuals with pre-existing dermatological conditions of the ear, such as seborrhoeic dermatitis or psoriasis. Bacterial infection is common in such cases, and prolonged use of topical antibiotics and corticosteroids will often result in fungal superinfection. [**/*]

CLINICAL MANIFESTATIONS

The initial symptoms of fungal and bacterial otitis externa are often indistinguishable. However, while pain is the dominant symptom in bacterial infection, the most common complaint in otomycosis is aural fullness and pruritis deep inside the canal.² Sometimes, discharge is present but it is not mucoid that would suggest that there is a tympanic perforation. Obstruction of the meatus can lead to partial hearing loss and tinnitus. Otoscopic examination often reveals the presence of debris and an oedematous and erythematous canal. If *A. niger* is the causative agent, a mat of fungus, often covered with black sporing heads, can be seen (**Figure 18.1**). This mass lining the meatus, which it can obstruct, is often described as resembling blotting paper. In chronic infections, eczematoid changes and lichenification of the canal can become marked. [**/*]

DIAGNOSIS

Fungal infection should be suspected when a patient with otitis externa fails to respond to topical antibiotics and

corticosteroids. Material taken for microscopic examination using a potassium hydroxide preparation will reveal branching hyphae, budding cells or both. In cases of *Aspergillus* infection, the typical sporing heads can sometimes be seen. Isolation of the aetiological agent in culture will enable the species of the fungus involved to be identified. [**/*]

MANAGEMENT OPTIONS

Treatment primarily consists of the removal of debris from the ear canal and thorough cleaning, together with the local application of an antifungal agent. Topical nystatin can be applied three times a day for two to three weeks. The local application of an imidazole cream, such as clotrimazole or econazole nitrate also gives good results. Another method is to insert gauze packs, soaked in amphotericin B or an imidazole preparation for one week and these should be replaced at frequent intervals. [Grade D] In developing countries, or when these agents are not readily available, mercurochrome solution and boric acid have been used with success. [Grade D]

OUTCOMES AND COMPLICATIONS

The majority of patients with otomycosis respond to treatment. Complications are rare, but include recurrence, or perforation of the tympanic membrane. Most perforations heal spontaneously, usually within a month.⁵ In immunosuppressed individuals (with haematological malignancies or end-stage acquired immune deficiency syndrome (AIDS)), the infection may progress to a necrotizing (malignant) otitis externa. This is most commonly caused by *A. fumigatus*, but *Scedosporium apiospermum* has also been implicated.⁶ [**/*]

Disease of the external ear

The external ear is sometimes the site of fungal infection. The commonest cause is dermatophytosis, with infection caused by *Trichophyton rubrum* being the most frequent. However, mycotic diseases of implantation, such as chromoblastomycosis and sporotrichosis, may also affect this site. The clinical manifestations are similar to those seen with cutaneous or subcutaneous infections caused by these organisms. [*]

© Hodder Arnold / Scott-Brown 7E

KEY POINTS

- Otomycosis is more commonly seen in adults and in tropical climates.
- The symptoms of otomycosis are often indistinguishable from bacterial otitis externa.

- Prolonged use of topical antibiotics and corticosteroids often leads to otomycosis.
- Laboratory tests are often required to confirm the diagnosis of otomycosis.
- Topical antifungal treatment is usually effective.

MYCOTIC DISEASES OF THE NOSE AND NASAL PASSAGES

Nasal involvement can occur when invasive aspergillosis or mucormycosis extends outside the paranasal sinuses. However, two diseases are specifically associated with nasal invasion: entomophthoromycosis and rhinosporidiosis.

Entomophthoromycosis

DEFINITION

This is a chronic localized subcutaneous fungal infection that originates in the nasal mucosa and spreads painlessly to the adjacent subcutaneous tissue of the face. This rare infection is seen in healthy individuals, but its progressive nature can lead to severe facial disfigurement.

AETIOLOGICAL AGENT

Conidiobolus coronatus is found in the soil and on decomposing vegetation in tropical rain forests. It is also an insect pathogen.

EPIDEMIOLOGY

The disease is most common in West Africa, in particular, Nigeria, but cases have also been reported from India, and from South and Central America.^{7,8} The disease can occur at any age, but is uncommon in children. Most cases affect men living or working in tropical rain forests. In most cases the organism is introduced on the soiled hands of the patient. In some instances, the infection follows spore inhalation. [**/*]

CLINICAL MANIFESTATIONS

The clinical appearances are typical. The spread of the infection from the nose to the facial tissues is slow but relentless leading to severe facial disfigurement. The commonest symptom is nasal obstruction, due to tissue expansion. Pain and ulceration are uncommon, but nasal discharge is frequent. The lesions have a distinct margin, but the mass is not movable over the underlying tissue. The swelling is hard but not tender. The skin remains intact. [**/*]

DIAGNOSIS

Even if, in advanced cases, the diagnosis is obvious from the typical clinical appearance, laboratory investigation is essential for its confirmation. The diagnosis is best established by microscopic examination of smears or tissue from the nasal mucosa. In haematoxylin-eosin stained tissue sections, the organisms appear as broad, nonseptate, thin-walled, irregularly branching hyphae and in some cases are surrounded by Splendore-Hoeppli material. Culture is difficult. [**/*]

MANAGEMENT OPTIONS

Patients often respond to oral treatment with fluconazole (200 mg/day), itraconazole (200–400 mg/day) or ketconazole (200–400 mg/day). [Grade D] Treatment should be continued for at least one month after the lesions have cleared. Saturated potassium iodide solution can be useful. The starting dose is 1 mL three times daily, and this is increased up to 4–6 mL three times daily as tolerated. [Grade D] Treatment must be continued for at least one month after the lesions have disappeared. Surgical resection of infected tissue is seldom successful; it may hasten the spread of infection.

OUTCOMES AND COMPLICATIONS

Relapse is common and can happen long after apparently successful treatment. [**/*]

Rhinosporidiosis

DEFINITION

This is an uncommon chronic granulomatous infection that affects the nasal mucosa, ocular conjunctiva and other mucosa.

AETIOLOGICAL AGENT

The causal agent of rhinosporidiosis is *Rhinosporidium seeberi*. In tissue, this organism forms characteristic abundant, large, thick-walled sporangium-like structures containing large numbers of endospores. It has long been unclear whether this organism is a fungus, but sequencing of the 18S small subunit ribosomal DNA sequence from *R. seeberi* has led to its recent reclassification as a member of the protoctistan Mesomycetozoa.⁹ Attempts to isolate *R. seeberi* in culture have failed and thus far it has not been recovered from an environmental source.

EPIDEMIOLOGY

The disease is most common in southern India and Sri Lanka, but sporadic cases have been reported from

East Africa, Central and South America, South East Asia and other parts of the world.¹⁰ The natural habitat of the organism is unknown, but it is believed, based on the epidemiologic data, that stagnant pools of fresh water are an important source. The disease is most prevalent in rural districts, among persons bathing in public ponds or working in stagnant water, such as rice fields. Rhinosporidiosis is most common in persons in the age range of 15–40; males are more commonly affected than females. [**/*]

CLINICAL MANIFESTATIONS

The nose is the commonest site of rhinosporidiosis, being affected in more than 70 percent of cases. The fungus causes the production of large sessile or pedunculated lesions that affect one or both nostrils. The infection is insidious in onset and the patient remains unaware of its existence until obstruction develops. Rhinoscopic examination will reveal papular or nodular, smooth-surfaced lesions that become pedunculated and acquire a papillomatous or proliferative appearance. The lesions are pink, red or purple in colour. In most cases the general health of the patient is unimpaired. Spontaneous remission is unusual and, left untreated, the polyps will continue to enlarge. [**/*]

DIAGNOSIS

The diagnosis is established by histopathologic examination of tissue sections. These contain large, round or oval sporangia up to 350 µm in diameter, with a thick wall and an operculum. The largest sporangia are filled with spores.

MANAGEMENT OPTIONS

The treatment of choice is surgical excision of lesions, with or without cauterization. No drug treatment has proved effective. [Grade D]

OUTCOMES AND COMPLICATIONS

Recurrence is common and patients should be followed up where possible. [**/*]

KEY POINTS

Entomophthoromycosis

- Entomophthoromycosis is a rare infection, but can lead to severe facial disfigurement.
- Laboratory tests are essential to confirm the diagnosis.
- Surgical resection is seldom successful and can hasten the spread of infection.
- Relapse is common after medical treatment.

Rhinosporidiosis

- Bathing or working in stagnant water is an important risk factor for rhinosporidiosis.
- Histopathological examination is important to confirm the clinical diagnosis.
- Medical treatment is ineffective.
- Patients often relapse following surgical removal of lesions.

MYCOTIC DISEASES OF THE PARANASAL SINUSES

Mycotic diseases of the paranasal sinuses range from an indolent infection in an otherwise normal person, to a lethal fulminant infection in an immunocompromised individual, reflecting the interaction between host and aetiological agent. Until the 1990s, no criteria for diagnosis or consensus on the classification of fungal sinusitis existed. Several recent investigations have addressed these problems and have led to the development of both diagnostic criteria and a new system of classification.^{11, 12, 13} Based on histopathologic findings and clinical presentation, fungal sinusitis is now classified into three categories: invasive sinusitis, noninvasive sinusitis and allergic fungal sinusitis.

Invasive fungal sinusitis

DEFINITION

Invasive fungal sinus disease can be subdivided into the following three syndromes: acute fulminant invasive sinusitis, chronic invasive sinusitis and chronic granulomatous invasive sinusitis or paranasal granuloma.^{11, 12, 13} The diagnosis of these disorders requires radiographic or nasal endoscopic evidence of sinusitis, together with histopathological evidence of the presence of fungal hyphae in the sinus mucosa, submucosa or bone.

Active invasive sinusitis

Acute fulminant (invasive) fungal sinusitis is a rapidly progressive disease that is most commonly seen in immunocompromised individuals or diabetics with uncontrolled ketoacidosis. Immunocompetent individuals are seldom affected. The infection can spread from the nasal mucosa and sinus into the orbit and brain. The aetiological agents have a predilection for vascular invasion, causing thrombosis, infarction and ischaemic necrosis of tissues.

Chronic invasive sinusitis

Chronic (invasive) fungal sinusitis is a slowly progressive disease that is seen in both immunocompromised and immunocompetent individuals. This condition may begin

as a paranasal sinus fungus ball (see under Noninvasive fungal sinusitis) and then become invasive, perhaps as a result of the immunosuppression associated with diabetes mellitus or corticosteroid treatment. If left untreated, the infection can spread to invade adjacent structures, including the orbit and brain.

Chronic granulomatous invasive sinusitis

Granulomatous invasive fungal sinusitis (paranasal granuloma) is a slowly progressive disease that occurs in immunocompetent persons who often have had chronic sinusitis. There is profuse fungal growth with localized tissue invasion, and noncaseating granulomas with giant cells. The granulomatous response is often intense enough to cause pressure necrosis of bone and can cause proptosis. Unless removed, the fungal mass can spread into the orbit and brain.

AETIOLOGICAL AGENTS

Many different organisms have been implicated as aetiological agents of invasive fungal sinusitis. However, the commonest causes of acute fulminant sinusitis are moulds belonging to the order Mucorales, including *Rhizopus* species, particularly *R. arrhizus*, *Absidia* species and *Rhizomucor* species. Other less frequent causes of fulminant sinusitis include *Aspergillus* species, particularly *A. flavus* and *A. fumigatus*, *Fusarium* species and *S. apiospermum*. Among the more important aetiological agents of chronic invasive sinusitis are *Alternaria* species, *Aspergillus* species, *Bipolaris* species, *Curvularia* species and *Exserohilum* species. Many of these organisms are ubiquitous in the environment, being found in the air, in soil and on decomposing organic matter; others are plant pathogens. [**]

Most cases of granulomatous invasive fungal sinusitis have been caused by *A. flavus* infection. [**/*]

EPIDEMIOLOGY

Acute invasive fungal sinusitis has a worldwide distribution. Most cases have been reported in adults, but immunocompromised children are also at risk; men and women are equally affected.^{14, 15, 16} The aetiological agents are ubiquitous in the environment, and the likelihood that infection will occur following inhalation of fungal spores largely depends on host factors. Prolonged neutropenia and metabolic acidosis are well recognized as important risk factors for rhinocerebral mucormycosis and fulminant aspergillus sinusitis among patients with haematological malignancies, haematopoietic stem cell transplant recipients and individuals with diabetes mellitus.^{14, 15, 16} Other contributing factors include the use of corticosteroids, deferoxamine treatment and human immunodeficiency virus (HIV) infection.^{14, 15, 16} [**]

Chronic invasive fungal sinusitis also has a worldwide distribution, but the largest number of cases has been

reported from North America. The more indolent invasive presentations are seen in both immunocompromised and immunocompetent individuals, including patients with well-controlled diabetes mellitus and those receiving corticosteroid treatment. Affected individuals often complain of long-standing allergic rhinitis, or chronic bacterial sinusitis. [**]

Most cases of granulomatous invasive fungal sinusitis occur in immunocompetent individuals and have been reported from North Africa. However, reports of this condition have also come from India, Pakistan and the United States. [**]

CLINICAL MANIFESTATIONS

In immunocompromised persons, acute invasive fungal sinusitis presents with fever, unilateral facial swelling, unilateral headache, nasal obstruction or pain and a serosanguinous nasal discharge.^{14, 15, 16} Necrotic black lesions on the hard palate or nasal turbinate are a characteristic diagnostic sign.^{14, 15, 16} As the infection spreads into the orbit, periorbital or perinasal swelling occurs and progresses to disfiguring destruction of facial tissue. Ptosis, proptosis, ophthalmoplegia and loss of vision can occur (**Figure 18.2**).^{14, 15, 16} [**]

Chronic invasive fungal sinusitis has been reported in nonimmunocompromised persons as well as in individuals who had received corticosteroids or had diabetes mellitus. Patients with AIDS can also present with this form of fungal sinusitis, although the classification in this population is not always clear.¹⁷ Many patients present with a history of nasal obstruction and chronic sinusitis.

Figure 18.2 An axial CT scan of chronic invasive aspergillosis in an elderly woman treated with steroids for polymyalgia rheumatica. She presented with blindness. Note the disease invading the cavernous sinus. She remains well 18 months later after 12 months of itraconazole.

Thick nasal polyposis and thick purulent mucus are common. If the infection spreads from the ethmoid sinuses into the orbit, the orbital apex syndrome is a common clinical presentation.^{11, 12, 13} This condition results from erosion of the fungal mass into the orbital apex causing impaired vision and restricted ocular movement. Proptosis can also occur. Chronic invasive sinusitis is often advanced by the time of diagnosis, with posterior erosion out of the ethmoid sinus, resulting in cavernous venous thrombosis. [**]

Granulomatous invasive fungal sinusitis (paranasal granuloma) occurs in immunocompetent persons who often present with long-standing symptoms of nasal obstruction, unilateral facial discomfort and/or enlarging mass, or with a silent proptosis.^{11, 12, 13} [**]

DIAGNOSIS

Imaging studies can assist in determining the presence and the anatomic extent of sinus disease, however, plain radiographs are insensitive and do not allow distinction between bacterial and fungal infections. Computed tomography (CT) scanning is more discriminating and can be used to assess the extent of bone destruction and pattern of sinus and orbital involvement. The commonest findings in patients with acute invasive fungal sinusitis include involvement of several sinuses (in particular ethmoid and sphenoid) but with a clear unilateral predilection, no air-fluid levels, thickening of sinus linings and destruction of surrounding bone.^{18, 19} Magnetic resonance imaging (MRI) is not clearly superior to CT, but it is deemed more accurate in providing information about cavernous sinus and cerebral involvement.¹⁹ [**]

In patients with chronic invasive sinusitis, noncontrast CT scans reveal a hyperdense mass (owing to a dense accumulation of fungal hyphae) within the involved sinus with associated erosion of the sinus walls.^{11, 13} The most common radiographic findings in patients with granulomatous invasive fungal sinusitis (paranasal granuloma) are opacification of ethmoid, maxillary or all sinuses (pansinusitis), together with erosion of bone. [**/*]

Local biopsy with histopathological examination and culture of tissue or sinus contents confirms the clinical and radiological diagnosis of invasive fungal sinusitis. In cases of acute invasive infection, where delay may have a serious impact on the outcome, the diagnosis is often best made by direct microscopic examination of a potassium hydroxide preparation of material taken from necrotic lesions. The Mucorales can be distinguished from other moulds, such as *Aspergillus* species, by their characteristic broad nonseptate hyphae with right-angled branching. It is not possible, however, to differentiate *Aspergillus* species from *Fusarium* species, *S. apiospermum* or other nonpigmented moulds by their microscopic appearance in tissue. All produce branching septate nonpigmented hyphae. Isolation of the aetiological agent in culture is

essential for the species of fungus involved to be identified. [**/*]

MANAGEMENT OPTIONS

If treatment of acute invasive fungal sinusitis is to be successful, a prompt diagnosis is essential. Underlying host disorders must be controlled: correction of acidosis is essential and immunosuppressive drugs should be reduced in dose if possible. Infected and necrotic tissue must be removed immediately and an effective antifungal agent must be administered. [Grade B]

In acute fulminant fungal sinusitis with invasion of blood vessels, amphotericin B has been considered the drug of choice (at a dose of 1–1.5 mg/kg per day). However, there is a growing consensus, based on animal models and retrospective clinical data, that the newer lipid-based formulations of the drug, in particular high doses of liposomal amphotericin B (10–15 mg/kg per day), should be considered the first line of treatment.²⁰ This should be continued until the patient recovers. [Grade B]

The optimum duration and total dose of amphotericin B that should be given in acute invasive sinusitis has not been determined. Treatment must be individualized according to the patient's clinical response and the rate of clearing of the infection. Treatment should be continued at least until progression of disease ceases and the underlying disorder is well controlled.

Itraconazole should not be regarded as a first-line agent against mucormycosis,²⁰ but its use may be considered for infections with susceptible organisms, such as *S. apiospermum*, that are resistant to amphotericin B. However, the optimum dosage and duration of treatment have not been defined. [Grade D] The role of voriconazole in acute invasive sinusitis is unclear. This drug is effective against *Aspergillus* species, but inactive against the Mucorales.²⁰ Posaconazole, a new broad-spectrum triazole, is active against *Aspergillus* species and the Mucorales. There are anecdotal reports of successful salvage treatment of acute rhinocerebral mucormycosis with this drug.^{21, 22} [Grade D]

Other treatment options of unclear effectiveness are administration of hyperbaric oxygen, iron chelators and cytokines.²⁰ The usefulness of these approaches cannot be evaluated on the basis of published uncontrolled reports.

In chronic invasive sinusitis, a histological diagnosis is needed to exclude blood vessel invasion found in acute fulminant fungal sinusitis. Invasion of adjacent structures is a common complication of chronic invasive fungal sinusitis. Extensive surgical debridement with removal of all necrotic material, combined with antifungal treatment, has been recommended. [Grade B] The optimum duration of itraconazole (100 mg bd) has not been defined. The role of the newer triazole antifungal agents, such as itraconazole, voriconazole and posaconazole, is

unclear but promising. [Grade D] There is evidence that long-term treatment with itraconazole can reduce the rate of recurrence following surgical resection or cure the condition on its own. [Grade D]

In patients with granulomatous invasive sinusitis, surgical removal of the paranasal granuloma has been recommended. Complete removal is often difficult and the condition can recur. However, there is some evidence that long-term oral treatment with itraconazole reduces the rate of recurrence [Grade C], or can cure the disease on its own.²³ [Grade D]

OUTCOMES AND COMPLICATIONS

More than 70 percent of diabetic patients with acute invasive fungal sinusitis will recover following prompt correction of acidosis, amphotericin B and aggressive surgical treatment.^{14, 15} In contrast, the outcome in individuals with other underlying disorders is less favourable. Factors associated with a lower survival rate include delayed diagnosis and treatment, hemiparesis or hemiplegia, bilateral sinus involvement, leukaemia, renal disease and treatment with desferrioxamine mesilate.^{14, 15} Survival is unusual in neutropenic patients with leukaemia in relapse.¹⁵ [**]

Although the combination of aggressive surgical debridement and amphotericin B treatment is recommended for the management of acute invasive sinusitis, it is not without complications. Surgical debridement is often mutilating and the conventional formulation of amphotericin B is nephrotoxic. Debridement carries the risk of bleeding in thrombocytopenic patients, as well as the risk of inadvertent damage to the orbit and brain. Patients who receive amphotericin B must be monitored for signs of renal damage. [**]

In patients with chronic invasive sinusitis, prolonged duration of symptoms prior to diagnosis and intracranial extension of the infection have been identified as factors associated with a lower survival rate.²⁴ According to a recent review of published cases of aspergillus sinusitis in immunocompetent individuals, the mortality rate for patients with intracranial extension was 44 percent, compared with 15 percent for those without intracranial infection. Furthermore, only 6 percent of patients with intracranial extension were cured by antifungal and surgical treatment, compared with 46 percent of those without intracranial infection.²⁴ [**]

No long-term follow up of patients with granulomatous invasive sinusitis has been published.

Noninvasive fungal sinusitis

DEFINITION

A paranasal sinus fungus ball (or sinus mycetoma) is a chronic noninvasive fungal infection that is seen in

immunocompetent persons. However, if immunocompromise should occur, then the condition may become invasive and life-threatening.^{25, 26} Fungus balls consist of a dense mass of fungal hyphae. They are sometimes found in the sinus cavities of patients undergoing investigation for chronic sinusitis, nasal obstruction, facial pain or other conditions.

AETIOLOGICAL AGENTS

Aspergillus fumigatus is the most frequently isolated organism.²⁵ Less commonly, other *Aspergillus* species (including *A. flavus*), *S. apiospermum* and *Alternaria* species have been incriminated.²⁶ These moulds are ubiquitous in the environment. In many cases, however, the content of sinus fungus balls has failed to grow on culture. [**]

EPIDEMIOLOGY

Older individuals appear to be more susceptible. The average age reported in one review of 29 cases was 64 years.²⁵ No cases have been reported in children, but women account for around 64 percent of published cases.²⁶ Associated medical conditions are uncommon. The incidence of allergic rhinitis is no higher than in the general population. [**/*]

CLINICAL MANIFESTATIONS

The symptoms are often similar to those of chronic bacterial rhinosinusitis, but sometimes patients are asymptomatic. Affected persons often present with long-standing symptoms of nasal obstruction, purulent nasal discharge, cacosmia (fetid smell) or facial pain.^{25, 26} The symptoms are often unilateral. Unusual symptoms include fever, cough, proptosis, epistaxis, and diplopia. Nasal polyps are found in 10 percent of patients.²⁶ [**]

The maxillary sinus is most commonly involved, with partial or complete opacification, bone thickening and sclerosis; occasionally bone destruction can occur. The sphenoid sinus is the second most common site of involvement (Figure 18.3). Frontal sinus involvement is uncommon. Air-fluid levels, which are characteristic of acute bacterial sinusitis, are uncommon in fungus balls of the paranasal sinuses. [**]

DIAGNOSIS

Various features are required to confirm the diagnosis of fungus ball of the sinuses.²⁵ First, CT scans should reveal partial or total opacification of the involved sinus, often associated with flocculent calcifications. Mucopurulent sinus material should be found at the time of surgical intervention. Histopathological investigation should reveal that this material is composed of a dense matted

Figure 18.3 An axial CT scan showing a mycetoma caused by aspergillosis of the sphenoid sinus. Note the reactive hyperostosis.

conglomeration of fungal hyphae, separate from but adjacent to the mucosa of the sinus. Histopathological investigation should also demonstrate no evidence of allergic mucin in the sinus or granulomatous reaction in the mucosa. There should be no fungal invasion of the mucosa, associated blood vessels or bone. [**]

MANAGEMENT OPTIONS

Surgical removal of the fungus ball is the treatment of choice.^{25, 26} No local or systemic antifungal medication is needed. [Grade B]

OUTCOME AND COMPLICATIONS

Recurrence is rare, but has been described as late as two years following the endoscopic removal of a paranasal fungus ball. Patients with sphenoid sinus balls are at risk of an intracerebral bleed or infarct as a complication of their surgical treatment. Patients who become immunosuppressed are at risk of developing an invasive fungal sinusitis. [**]

Allergic fungal sinusitis

DEFINITION

Allergic fungal sinusitis is a noninvasive disorder, seen in immunocompetent individuals, which is increasingly

being recognized as a cause of chronic rhinosinusitis. The reported incidence of this disorder ranges from 5 to 10 percent of patients with chronic rhinosinusitis in some studies,^{27, 28} to a much higher percentage in others.²⁹ The criteria for diagnosis of this condition have undergone numerous revisions, however, most authors agree on the following: the presence in patients with chronic rhinosinusitis (confirmed by CT scan) of characteristic 'allergic' mucin containing clusters of eosinophils and their byproducts; and the presence of noninvasive fungal elements within that mucin detectable on staining or culture.^{27, 28, 29, 30} Most experts also require the presence of documented type 1 (immunoglobulin (Ig)E-mediated) hypersensitivity to cultured fungi, and nasal polypsis.^{27, 28, 30} The diagnosis of allergic fungal sinusitis should not, however, be established, or eliminated, on the basis of the results of the fungal cultures because of the variable yield of these cultures.³⁰

In 1999, Ponikau *et al.*,²⁹ using ultrasensitive mucus collection and staining methods, reported finding fungus in nasal mucus from 202 (96 percent) of 210 consecutive patients with chronic rhinosinusitis at the Mayo Clinic, as well as 14 of 14 control patients. Allergic mucin, containing degenerating eosinophils and their byproducts, was found in 97 (96 percent) of a subset of 101 consecutive patients who underwent surgical treatment; in the four cases in which allergic mucin was absent, eosinophils were also absent. Fungal elements were detected in histopathological specimens from 82 (81 percent) of these 101 cases. Conventional IgE-mediated hypersensitivity to fungi was not a consistent finding in the patients with chronic rhinosinusitis. These observations led Ponikau *et al.*²⁹ to conclude that allergic fungal sinusitis is an underdiagnosed disorder that is, in fact, present in most patients with chronic rhinosinusitis. More recently, an Austrian group³¹ used the Mayo Clinic procedure and detected fungus in cultures of nasal mucus from 87 percent of patients with chronic rhinosinusitis, as well as from 91.3 percent of a control group. Ponikau *et al.*²⁹ speculated that IgE-mediated type 1 hypersensitivity to fungi is not the dominant pathophysiological mechanism, rather this role is played by eosinophils. They suggested that the disorder be renamed 'eosinophilic fungal sinusitis'. These conclusions have proved controversial and have been criticized on the grounds that the 'causative agents' (i.e. fungi) were detected in all the control subjects, and because of the small number of cases studied in which eosinophils were not found in tissue specimens. The current consensus is that the term 'allergic fungal rhinosinusitis' should be retained for the subgroup of patients with classical distinct immunologic, allergic, clinical and histologic features.³⁰

The term 'eosinophilic mucin rhinosinusitis' has been proposed to describe those patients with chronic rhinosinusitis and allergic mucin in whom no fungal elements can be detected.³² It has been suggested that allergic fungal sinusitis is an allergic response to fungi in

predisposed individuals, while eosinophilic mucin rhinosinusitis represents a heterogeneous group of pathophysiological mechanisms all associated with eosinophilia, but in which the predominant mechanism is a systemic dysregulation of immunological controls.

AETIOLOGICAL AGENTS

In earlier reports, *Aspergillus* species were believed to be the predominant cause of allergic fungal sinusitis. More recent series suggest that it is predominantly due to various dematiaceous (brown-pigmented) environmental moulds, including *Alternaria*, *Bipolaris*, *Cladosporium*, *Curvularia* and *Drechslera* species.²⁸ [**]

EPIDEMIOLOGY

This condition occurs in young immunocompetent adults with chronic relapsing rhinosinusitis, unresponsive to antibiotics, antihistamines or corticosteroids. Although patients do not have underlying immunodeficiencies, 50–70 percent are atopic.²⁸ There is no male or female predominance. Cases of allergic fungal sinusitis have been described from different parts of the world, but the largest number of reports have come from the warm humid areas of the southern United States where the disorder accounts for about 7 percent of all sinus surgeries. [**]

CLINICAL MANIFESTATIONS

Many patients with allergic fungal sinusitis have a history of chronic rhinosinusitis and have undergone multiple operations prior to diagnosis.^{27, 28} Although there are no unique pathognomonic symptoms, patients often present with unilateral nasal polyposis and thick yellow-green nasal or sinus mucus. The nasal polyposis may form an expansive mass that causes bone necrosis of the thin walls of the sinuses. Should the lamina papyracea of the ethmoid bone be traversed it may cause proptosis. Polypoid material can also push the nasal septum into the contralateral airway. CT scans often reveal a characteristic serpiginous sinus opacification of more than one sinus, mucosal thickening and erosion of bone, but this does not represent tissue invasion (**Figure 18.4**). In addition, allergic fungal sinusitis may be suspected when a patient with nasal polyposis, having no other known disease, responds only to oral corticosteroids. [**]

DIAGNOSIS

The diagnosis of allergic fungal sinusitis requires the presence of chronic rhinosinusitis in an otherwise immunocompetent individual; the microscopic examination of the characteristic allergic mucin (either at the time of surgical debridement for chronic sinusitis or

Figure 18.4 A coronal CT scan showing allergic polyposis due to aspergillosis of the paranasal sinuses with expansion into the orbit and anterior cranial fossa simulating invasive disease. The patient had raised IgE levels to *Aspergillus*. At surgery the dura and periosteum were intact, histologically *Aspergillus* was present with Charcot Leyden crystals and there was no invasion. The patient remains well five years after surgery and topical nasal steroids.

endoscopic examination for drainage) to determine the presence of eosinophils and fungal elements; histologic examination of sinus tissue to rule out invasion; radiographic studies to assess the extent of disease; and laboratory testing for eosinophilia, total serum IgE, specific IgE against fungal antigens, and a positive skin prick test to fungal antigens. Fungal cultures are used to identify the responsible fungus. [**]

MANAGEMENT OPTIONS

The treatment of allergic fungal sinusitis includes surgical debridement to remove polyps and the allergic mucin containing fungal debris which is thought to be the cause of the immune reaction in the sinus mucosa. [Grade B] More than one surgical procedure may be required to accomplish this goal. Adjunctive medical management is also required because it is unlikely that all fungal elements can be removed. In small studies, use of postoperative oral corticosteroids reduced recurrence of disease.^{33, 34} [Grade D] Other commonly used adjunctive medical treatments for allergic fungal sinusitis include specific allergen immunotherapy, nasal corticosteroids, antihistamines, antileukotrienes and sinonasal saline lavage.³² However, there have been no controlled studies. [Grade D]

Systemic antifungal drug treatment has not proved effective for the management of allergic fungal sinusitis other than preoperatively to reduce swelling and preoperative bleeding. In most cases, even patients whose symptoms, endoscopic signs and CT scans cleared with systemic antifungal treatment relapsed soon after this was discontinued.³⁵ [Grade D] There is poor evidence that topical antifungal treatment might be of benefit in allergic fungal sinusitis.

OUTCOMES AND COMPLICATIONS

Postoperative endoscopic follow up is recommended because there is a poor correlation between subjective improvement and the presence of objective regression of disease. Despite surgical debridement and corticosteroid treatment, the condition recurs in up to two-thirds of patients. In addition, corticosteroid use is sometimes associated with limiting side effects. [**]

KEY POINTS

Fulminant acute invasive sinusitis

- The infection often spreads into the orbit and brain.
- Prolonged neutropenia and metabolic acidosis are important risk factors.
- The commonest aetiological agents are moulds belonging to the order Mucorales.
- For treatment to be successful, prompt diagnosis is essential.
- Aggressive medical and surgical treatment are both required.
- Blood vessel invasion is seen histologically.

Chronic invasive sinusitis

- The most common aetiological agents include *Aspergillus*, *Bipolaris* and *Curvularia* species.
- Invasion of adjacent structures is a common complication.
- MRI is useful for assessing cavernous sinus and cerebral involvement.
- Medical treatment is sufficient in most cases.
- Itraconazole (100 mg bd) results in remineralization of the eroded skull base.

Chronic granulomatous invasive sinusitis

- Most cases have been reported from North Africa.
- *A. flavus* is the most common aetiological agent.
- Medical treatment is itraconazole 100 mg bd.
- Complete surgical removal of the granuloma is difficult.

Noninvasive fungal sinusitis

- Paranasal sinus fungus balls are most often seen in older persons.
- *A. fumigatus* is the commonest aetiological agent.
- The symptoms are often unilateral and include nasal obstruction, purulent discharge and cacosmia.
- CT scans should reveal partial or total opacification of the involved sinus.
- Surgical removal of the fungus ball is the recommended treatment.

Allergic fungal sinusitis

- Allergic fungal sinusitis is an important cause of chronic rhinosinusitis.
- The criteria for diagnosis of this condition are:
 - characteristic allergic mucin
 - clusters of eosinophils
 - Charcot Leyden
 - the presence of fungal organisms detectable on staining and culture
 - the presence of type I hypersensitivity.
- The predominant causes of this condition are dematiaceous (brown-pigmented) moulds.
- Management includes surgical debridement with adjunctive medical treatment.
- Systemic antifungal treatment is ineffective on its own, but may reduce inflammation and perioperative bleeding and if given postoperatively may reduce the recurrence rate.

Best clinical practice

Acute invasive sinusitis

- ✓ Underlying host disorders must be controlled: correction of acidosis is essential and immunosuppressive drugs should be reduced in dose if possible.
- ✓ Aggressive surgical debridement of infected and necrotic tissue is essential.
- ✓ Lipid-based formulations of amphotericin B, in particular high doses of the liposomal formulation (10–15 mg/kg per day), are considered the first choice treatment.
- ✓ Patients who receive amphotericin B should be monitored for signs of renal damage.
- ✓ Treatment should be continued at least until progression of disease ceases and the underlying disorder is well controlled.

Chronic invasive sinusitis

- ✓ Itraconazole (200 mg bd) has made surgery unnecessary in most cases.
- ✓ It is important to exclude fulminant acute sinusitis by histology.

MYCOTIC DISEASES OF THE THROAT

With the exception of pharyngeal candidiasis (which occurs as an extension of oral disease), mycotic infections of the pharynx and larynx are uncommon in ear, nose and throat practice.

Candidiasis

DEFINITION

The term candidiasis is used to refer to infections caused by organisms belonging to the genus *Candida*. These opportunistic pathogens can cause acute or chronic deep-seated infection, but are more often seen causing mucosal, cutaneous or nail infection. Oropharyngeal candidiasis is a common problem in debilitated or immunocompromised persons. Isolated laryngeal candidiasis can also occur in these individuals, but is much less common.

AETIOLOGICAL AGENTS

Oropharyngeal and laryngeal candidiasis is most commonly caused by *C. albicans*. However, several other members of the genus, including *C. glabrata*, *C. krusei*, *C. tropicalis* and *C. parapsilosis*, have sometimes been associated with oropharyngeal disease. [***/**]

EPIDEMIOLOGY

In most cases, infection is derived from an individual's own endogenous reservoir in the mouth and upper respiratory tract. *Candida albicans* is present as a commensal in the mouth of up to 40 percent of the normal adult population. The number of organisms in the saliva of carriers increases with tobacco smoking and when dentures are worn. [***/**]

Both general and local predisposing factors are important in the development of oropharyngeal and laryngeal candidiasis. Debilitated patients, such as those receiving broad-spectrum antibiotics or corticosteroids, patients with diabetes mellitus, individuals with severe nutritional deficiencies and immunosuppressive diseases, such as AIDS, are more susceptible to oropharyngeal candidiasis. Local factors, such as trauma from unhygienic or ill-fitting dentures and tobacco smoking, are also important. Isolated laryngeal candidiasis has usually been

described in immunocompromised patients, but it may also occur in immunocompetent individuals. Most patients have some associated disease and/or predisposing factors. These include previous radiation therapy, broad-spectrum antibiotics and corticosteroid use. [***/**]

Prior to the introduction of combination antiretroviral treatment, oropharyngeal candidiasis was the most common opportunistic infection seen in persons with HIV infection. Up to 90 percent of untreated HIV-positive individuals developed candidiasis at some time during the course of HIV disease.³⁶ Furthermore, oropharyngeal candidiasis occurred in about 60 percent of those with a CD4 cell count of less than 100–200 cells/mm³, more than half of whom experienced recurrent infection.³⁶ Recent epidemiological data indicate that the incidence of oropharyngeal and oesophageal candidiasis has fallen since the widespread introduction of new antiretroviral therapies, including protease inhibitors, perhaps by as much as 50–60 percent.³⁷ The development of oropharyngeal candidiasis is often one of the earliest clinical manifestations of HIV infection in asymptomatic individuals and is a reliable marker of disease progression. Although it is not life-threatening, it can be most uncomfortable for the patient, contributing to inadequate oral nutrition and weight loss. Of greater concern, it can predispose patients to develop a more invasive disease, such as oesophageal candidiasis. [***/**]

CLINICAL MANIFESTATIONS

Oral candidiasis can be classified into a number of distinct clinical forms: pseudomembranous, erythematous (or atrophic) and hyperplastic (or hypertrophic) candidiasis.

Pseudomembranous candidiasis is an acute infection, but it can recur in patients using steroid inhalers and in immunocompromised individuals. It is also seen in neonates and among terminally ill patients, particularly in association with serious underlying disorders, such as leukaemia and other malignancies. It is the most common form of candidiasis in HIV disease. Pseudomembranous candidiasis presents as white raised lesions on the surfaces of the tongue, hard and soft palate, buccal mucosa and tonsils. If left untreated, these can develop to form confluent plaques. The lesions are often painless, although mucosal erosion and ulceration may occur. The infection may spread to involve the throat, giving rise to severe dysphagia. It is important to distinguish this condition from hyperplastic candidiasis (oral leukoplakia). The simplest test is to determine whether the white pseudomembrane can be dislodged. If it can be wiped off to reveal an eroded, erythematous, and sometimes bleeding base, then this is diagnostic for pseudomembranous candidiasis. [**]

Erythematous candidiasis is often associated with broad-spectrum antibiotic treatment, chronic corticosteroid use and with HIV disease. It can arise as a

consequence of persistent pseudomembranous candidiasis, when pseudomembranes are shed, or, in HIV infection, may precede pseudomembranous candidiasis. It can affect any part of the oral mucosa and manifests as a flat, red lesion, usually on the palate or dorsum of the tongue. Lesions on the tongue present as depapillated areas. [**]

Hyperplastic candidiasis (candida leukoplakia) is an important condition because the lesions can undergo malignant transformation. The lesions range from small, palpable, translucent white areas to large, dense opaque plaques, hard and rough on palpation. In contrast to the pseudomembranous form of oral candidiasis, the lesions cannot be removed. The lesions usually occur on the inside surface of one or both cheeks and, less commonly, on the tongue. They are usually asymptomatic. Lesions that contain both red erythroplakic and white leukoplakic areas must be regarded with great suspicion as malignant change is often present. [**]

In addition to the foregoing three major forms of oropharyngeal candidiasis, there are several other lesions associated with candida infection. Chronic atrophic candidiasis (or denture stomatitis) is usually associated with oral prostheses, occurring in up to 60 percent of denture wearers. Apart from soreness, the condition is usually asymptomatic. The only presenting complaint may be associated angular stomatitis (or cheilitis). Lower dentures are seldom involved. The characteristic presenting signs are chronic mucosal erythema and oedema of the portion of the hard palate that comes into contact with the fitting surface of the upper denture. The condition is mainly due to the overgrowth of *C. albicans* beneath the dentures. The mucosa beneath the dentures is rarely involved. [**]

Hoarseness and dysphagia are the most common symptoms of laryngeal candidiasis. Some patients present with stridor. The characteristic signs of the infection are white plaques on the laryngeal mucosa. If left untreated, the infection can progress to airway obstruction. [**]

DIAGNOSIS

The clinical manifestations of oropharyngeal candidiasis are often characteristic, but can be confused with other disorders. For this reason, the diagnosis should be confirmed by demonstration of the various morphological forms of the fungus in smears prepared from swabs or scrapings of lesions and its isolation in culture. As *C. albicans* is a normal commensal in the mouth, its isolation alone cannot be considered diagnostic of infection. [**]

The diagnosis of laryngeal candidiasis should be considered in any immunodeficient patient presenting with symptoms of laryngeal disease. The most effective diagnostic procedure is fiberoptic or indirect laryngoscopy.³⁸ Mucosal biopsy specimens should be submitted for histopathological examination and culture. [**]

MANAGEMENT OPTIONS

In infants, pseudomembranous candidiasis can be treated with nystatin oral suspension (100,000 units/mL) or amphotericin B oral suspension (100 mg/mL). This should be dropped into the mouth after each feed or at four to six hour intervals. In most cases the lesions will clear within two weeks. [Grade D] Older children and adults with pseudomembranous candidiasis can be treated with clotrimazole troches (one 10-mg troche five times daily) nystatin or amphotericin B oral suspension (1 mL at six hour intervals for about two to three weeks) or miconazole oral gel (250 mg at six hour intervals). Treatment should be continued for at least 48 hours after all lesions have cleared and symptoms have disappeared. [Grade C/D]

Oral fluconazole (100–200 mg/day for 7–14 days) has been found to be more effective than ketoconazole in controlling oropharyngeal candidiasis in AIDS patients.^{39, 40} [Grade B] Itraconazole capsules (200–400 mg/day for 14 days) are as effective as ketoconazole.^{39, 40} [Grade B] Itraconazole oral solution (200–400 mg/day for 7–14 days) is better absorbed than the capsules, and it is as effective as fluconazole.^{39, 40} [Grade B] This may reflect the improved absorption of the solution or an additional topical effect.

Chronic suppressive treatment with fluconazole is effective in the prevention of oropharyngeal candidiasis in both AIDS and cancer patients.⁴⁰ To reduce the likelihood of development of antifungal resistance, it should only be used if recurrence is frequent or disabling. [Grade C] Up to two-thirds of AIDS patients with fluconazole-resistant oropharyngeal candidiasis will respond to itraconazole oral solution.^{39, 40} [Grade B] Amphotericin B oral suspension (1 mL at six hour intervals) is sometimes effective in patients who do not respond to itraconazole. [Grade C] Refractory candidiasis can be managed with parenteral amphotericin B (0.3–0.5 mg/kg per day for one week) or caspofungin (50 mg/day).⁴⁰ [Grade B]

The treatment of choice for laryngeal candidiasis is parenteral amphotericin B (0.7–1.0 mg/kg per day).⁴⁰ [Grade D] Oral fluconazole may be appropriate for treatment once symptoms and signs are improving.⁴⁰ [Grade D] Airway obstruction is managed by endotracheal intubation. [Grade D]

OUTCOMES AND COMPLICATIONS

Most individuals with oropharyngeal candidiasis will respond initially to topical or oral antifungal treatment. Prior to the introduction of the new highly active antiretroviral drug regimens, up to 60 percent of patients with HIV disease relapsed within three months of the successful completion of azole treatment for oropharyngeal candidiasis. However, recent data indicate that the incidence of relapse has decreased.³⁷ In HIV-positive individuals, symptomatic relapses are apt to occur sooner

with topical than with oral azole treatment. Resistance can develop with either regimen, but it is important to recognize that recurrence does not necessarily denote the development of resistant *C. albicans* strains, nor does it imply that the recurrent episode will be unresponsive to standard treatment.^{39, 40} [****/***]

Most patients with laryngeal candidiasis will respond to amphotericin B treatment. If not diagnosed and treated promptly, airway obstruction and, potentially, respiratory arrest can ensue. [**]

Other mycotic infections of the pharynx and larynx

A number of fungi can cause pharyngeal and laryngeal lesions as part of a disseminated mycosis. The most frequently seen of the systemic infections to affect this site are histoplasmosis and paracoccidioidomycosis. Occasional cases of blastomycosis, coccidioidomycosis and cryptococcosis have also been reported. [**]

Histoplasmosis and paracoccidioidomycosis both present in a similar way, usually with hoarseness or altered vocalization. Patients sometimes complain of sore throat, dysphagia, dyspnoea and cough.^{41, 42} Laryngoscopy will reveal an ulcer or granuloma on the vocal chords or on the laryngeal epithelium. The lesions are similar to those of laryngeal cancer, and biopsy with histopathological examination and culture is essential to establish the diagnosis.^{41, 42} [**/*]

Treatment of these infections is similar and, for paracoccidioidomycosis and histoplasmosis, itraconazole (200–400 mg/day for 6–18 months) is the drug of choice. [Grade D] Ketoconazole (200–400 mg/day) is also effective, but is less well tolerated than itraconazole. [Grade D] Lesions in the pharynx and larynx are usually part of a chronic disseminated infection and it is important to investigate the patient for other sites of involvement, including the oral mucosa, adrenals, lymph nodes, heart, liver and lungs.

Delay in the diagnosis may worsen the prognosis. In the case of paracoccidioidomycosis, the onset of fibrosis may cause laryngeal stenosis with permanent problems in both breathing and speech. Once it has been established it is not possible to stop fibrotic scarring. Other deep fungal infections in this site seldom cause such severe fibrosis. [**]

Mycotic colonization of tracheo-oesophageal voice prostheses

Silastic tracheo-oesophageal voice prostheses, which are used for speech rehabilitation in laryngectomized cancer patients, often deteriorate and require replacement. This deterioration is usually associated with biofilm formation

and invasion of the structure of the silastic by *Candida* species, including *C. albicans*, *C. glabrata*, *C. krusei* and *C. tropicalis*. This can occur within two to four months of implantation. In one report, 257 prosthesis replacements were required in a group of 31 patients over a 40-month period.⁴³ Radiation therapy-induced xerostomia was an important factor in shortening the lifetime of the prostheses that required replacement. [**]

Fungal damage to silastic tracheo-oesophageal prostheses results in valve failure and necessitates the replacement of the device. Local antifungal treatment is inadequate to eliminate deep infiltration of *Candida* species into the silastic material. However, a double-blind randomized trial has shown that the use of a buccal bioadhesive slow-release tablet containing miconazole nitrate might be an adequate method of preventing fungal colonization and deterioration.⁴⁴ [Grade C] Another potential new approach is metal coating of prostheses to prevent the adhesion of microorganisms.⁴⁵

KEY POINTS

- Oropharyngeal candidiasis is common in debilitated or immunocompromised persons.
- It is one of the earliest clinical manifestations of HIV infection, but has fallen in incidence since the introduction of combination antiretroviral therapies.
- Topical or oral antifungal treatment is usually highly effective.
- Azole drug resistance can develop in HIV-positive individuals receiving long-term treatment for recurrent infection.

Best clinical practice

- ✓ Because the clinical manifestations of oropharyngeal candidiasis can be confused with other disorders, the diagnosis should be confirmed by microscopic examination and culture.
- ✓ Patients can often be managed with topical clotrimazole, miconazole or nystatin.
- ✓ In persons with AIDS, oral fluconazole is more palatable than itraconazole oral solution, and more effective than ketoconazole.
- ✓ To reduce the likelihood of resistance developing, long-term azole treatment should be avoided unless relapse is frequent or disabling.
- ✓ Patients unresponsive to azole treatment can be managed with amphotericin B or caspofungin.

Deficiencies in current knowledge and areas for future research

- The role of azole antifungals, in particular voriconazole and posaconazole, in the treatment of acute invasive sinusitis is unclear and needs to be evaluated.
- The role of fungi in the pathogenesis of chronic sinusitis needs to be determined, as does the role of antifungal and other adjunctive medical treatments in the management of this disorder.

SEARCH STRATEGY

The information in this chapter is supported by a Medline search of review articles using the key words antibiotic, antifungal and antimicrobial resistance.

INTRODUCTION

The discovery of potent nontoxic chemotherapeutic agents selectively active against bacteria in the late 1930s revolutionized the treatment of infections. Unfortunately, microbes have demonstrated their ability to avoid, withstand or repel the antimicrobial onslaught. In addition, the pattern of infection has altered considerably, due to the impact of new operative and invasive procedures, and treatment regimens that severely compromise the patient's own capacity to withstand infection. No antimicrobial drug is entirely free from toxic side effects, and the use of antibiotics can disturb the delicate bacterial ecology of the body allowing the proliferation of resistant organisms. In the last two decades the pace of the development of antibiotic resistance has been faster than the development of new antibacterial agents, resulting in antibiotic resistance becoming a major threat to the effective treatment of infections, both in the community and in hospital. Thus, penicillin therapy can no longer be relied upon for the empirical treatment of pneumococcal meningitis and with the continuing rise of methicillin-resistant *Staphylococcus aureus* (MRSA) isolation rates, flucloxacillin therapy is under threat.¹ [**] Both national (UK) and international concern has risen since the late 1990s, with the formation of working parties to try and

stem the rising tide of antimicrobial resistance. These have identified the association of antimicrobial resistance with the use and abuse of antibiotics, and have emphasized the importance of the appropriate use of antibiotics, education on antimicrobial therapy and the proper selection of patients for treatment.^{2,3} [*]

The aim of this chapter is to explore the principles of antimicrobial therapy, provide brief details on the mechanism of action, spectrum of antimicrobial activity and pharmacokinetic features of each of the main classes of antimicrobials, and give a brief description of resistance mechanisms and adverse effects of antimicrobial agents.

PRINCIPLES OF ANTIMICROBIAL THERAPY

Effective treatment of an infection is based on the knowledge of the likely infecting organisms and antimicrobial susceptibility, the natural history of the disease, the site of the infection, the spectrum of action of antimicrobial agents and the risk of the treatment. Knowledge of the pharmacokinetics of an antimicrobial agent is important in ensuring that the agent reaches the site of the infection. Infection in difficult sites, such as cerebrospinal fluid (CSF), cannot be treated by an antimicrobial agent which does not cross the blood-brain

barrier in sufficient amounts at nontoxic doses. The pharmacological principles which apply to other drugs apply to antimicrobial agents, so that lipid-soluble agents such as chloramphenicol are well absorbed orally and cross the blood–brain barrier. Conditions at the site of infection can affect the activity of the antimicrobial agent, for example the lower pH found in an abscess reduces the efficacy of aminoglycosides and macrolides. The route of excretion can also affect the efficacy of an antimicrobial agent, for example those which are excreted in the urine are more likely to be effective in urinary tract infections.

Where antimicrobials are being used for surgical prophylaxis they should be administered immediately before or during a procedure and there is no published benefit from extending the duration of prophylaxis beyond wound closure. By giving extended prophylaxis the risks of treatment outweigh the benefit, due to the potential for further disturbance to the patient's natural flora and hence selecting for resistant organisms or infection with *Clostridium difficile*.

The antimicrobial activity of antibiotics depends on the bacterial target site, the ability of the antibiotic to get to that target site and whether the bacteria can break down the antibiotic before it is able to act. The cellular target sites for the main antibiotics are summarized in **Figure 19.1**. Similar principles apply to antifungal and antiviral agents.

ANTIMICROBIAL ACTIVITY AND PHARMOKINETICS

Antibiotics

INHIBITORS OF BACTERIAL CELL WALL SYNTHESIS

The bacterial cell wall is a common target as it differs from that of human cells. The structure is different in Gram-negative and -positive organisms and, in addition, some bacteria, such as chlamydiae, do not possess a bacterial cell wall.

β-LACTAM ANTIBIOTICS

Penicillins, cephalosporins, monobactams and carbapenems are similar compounds, containing a β-lactam ring, which mimics the cross-link of the peptidoglycan 'backbone' of the cell wall. Inhibition of this cross-linking occurs, weakening the cell wall and resulting in cell death by lysis.

PENICILLINS

Penicillins vary markedly in their oral absorption, penicillin V and aminopenicillins are absorbed orally but the remainder have to be given parenterally. They are divided on the basis of bacterial activity.

Figure 19.1 Bacterial sites of activity of the main classes of antibiotics.

- Natural penicillins, e.g. penicillin V: Gram-positive bacteria including streptococci, clostridia and corynebacteria (excluding most staphylococci), and some Gram-negative cocci including meningococci and most anaerobes (excluding *Bacteroides fragilis*).
- Penicillinase-resistant penicillins, e.g. flucloxacillin: As above with additional activity against penicillin-resistant *Staphylococcus aureus*.
- Aminopenicillins, e.g. ampicillin, and expanded-spectrum penicillins, e.g. piperacillin: Additional activity against Gram-negative bacilli including haemophili and many of the enterobacteriaceae. The expanded-spectrum penicillins have increased activity against enterobacteriaceae and pseudomonads, but resistance is increasing.
- Carbapenems, e.g. imipenem: Broad spectrum against Gram-positive and negative bacteria, including the β -lactamase producing Gram-negative organisms and anaerobic activity including *B. fragilis*.
- Monobactams, e.g. aztreonam: No Gram-positive but good Gram-negative activity including pseudomonads.
- β -lactamase inhibitors, e.g. clavulanic acid: In combination with a β -lactam with similar pharmacokinetic properties they have increased activity against anaerobes and enterobacteriaceae.

The most serious but uncommon side effect is acute anaphylaxis. Other allergic manifestations include angio-neurotic oedema, urticaria, Stevens-Johnson syndrome, dermatitis, morbilliform eruptions and allergic vasculitis. Reversible neutropenia sometimes occurs with prolonged high-dose penicillin therapy. High-dose therapy in renal failure can precipitate epilepsy if dose adjustments are not made. Diarrhoea including *C. difficile* infection is more commonly associated with ampicillin and amoxicillin.

Penicillins are used to treat streptococcal infections (including pneumococcal meningitis once penicillin sensitivity is confirmed), meningococcal and penicillin-sensitive gonococcal infections. Aminopenicillins are used to treat upper and lower respiratory tract infections, as they are also active against *Haemophilus influenzae*, whereas the penicillinase-resistant penicillins are used to treat methicillin-sensitive staphylococcal infections, as the majority of *S. aureus* isolates are resistant to penicillin due to the production of penicillinase.

CEPHALOSPORINS

These compounds are closely related to the penicillins and classified into four main generations.

The first-generation cephalosporins, such as cefradine are absorbed well orally; the second-generation cephalosporins are usually given intravenously but are available in oral formulations. The third-generation cephalosporins are injectable agents, cefotaxime and ceftriaxone are able to cross the blood-brain barrier in sufficient amounts to be used to treat meningitis.

As Gram-negative activity increases Gram-positive activity decreases. The first-generation cephalosporins are more active against methicillin-sensitive *S. aureus* and streptococci, while the third- and fourth-generation cephalosporins have increased Gram-negative activity and some pseudomonal activity, for example ceftazidime. They are not active against enterococci and, except for some of the fourth-generation compounds, are not active against *B. fragilis*.

There is a low incidence of anaphylaxis, but cross-reactivity in approximately 10 percent of penicillin-allergic patients, and rashes can occur. The third-generation cephalosporins are associated with a higher risk of *C. difficile* diarrhoea.

GLYCOPEPTIDES, FOR EXAMPLE VANCOMYCIN AND TEICoplanin

They affect bacterial cell wall synthesis by binding to the D-alanine of the peptide chain of Gram-positive cell walls inhibiting the cross-linking process. They only have Gram-positive activity as they are unable to penetrate Gram-negative cell walls. Resistance is uncommon but increasing, particularly in enterococci. As they are large molecules they are not absorbed orally and do not penetrate the blood-brain barrier and 80 percent of the drug is excreted in the urine. 'Red-man' syndrome can occur with rapid infusions of vancomycin due to the release of histamine and renal toxicity with high serum levels, which is more likely with the concomitant use of aminoglycosides. These toxic effects are minimized by dosage schedules and monitoring of serum levels. They are used for treatment of sepsis due to resistant Gram-positive infections, such as MRSA, or if the patient is penicillin allergic. Orally, vancomycin is a second-line therapy for *C. difficile* diarrhoea.

Inhibitors of nucleic acid synthesis

QUINOLONE ANTIBIOTICS, FOR EXAMPLE CIPROFLOXACIN

They interfere with the bacterial enzyme DNA gyrase which is required for supercoiling of DNA during transcription and replication. Nalidixic acid had limited Gram-negative activity, and the fluoroquinolones have replaced it with increased Gram-negative, pseudomonal and Gram-positive activity due to the addition of a fluorine atom. The newer quinolones are active against anaerobic bacteria and streptococci. There is good oral absorption and wide tissue distribution except for the CSF. Adverse effects include central nervous system effects which include epileptic seizures, and interaction with other drugs, such as increasing theophylline levels. Photosensitivity has been a problem with some of the newer quinolones and also limited use. Invasive Gram-negative infections, particularly where pseudomonal

infection is a possibility, and more difficult infections, such as typhoid, are typical clinical uses. The rise in resistance, particularly in *Salmonella typhi* and *Neisseria gonorrhoeae*, is beginning to limit their use.

SULPHONAMIDES AND TRIMETHOPRIM

These interfere with bacterial folic acid synthesis, and as they act at different stages producing synergistic activity in combination, for example co-trimoxazole, and display good oral absorption and tissue penetration. They have Gram-positive and -negative activity, and activity against *Pneumocystis carinii* and *Nocardia* sp., but resistance in enterobacteriaceae has increased. Sulphonamides are associated with severe allergic skin rashes including Stevens-Johnson syndrome. Combination agents are only licensed for severe infections in the UK. Trimethoprim is used in isolation for simple urinary and respiratory tract infections.

RIFAMYCINS

Rifamycins inhibit DNA-dependent RNA polymerase with inhibition of transcription to mRNA. Although good Gram-positive and mycobacterial activity, with some Gram-negative activity, for example meningococci, is shown, resistance develops rapidly if used as a single agent. They are well absorbed orally with good tissue, CSF and intracellular penetration. Hepatitis and occasionally haemolytic anaemia are important adverse effects used for prophylaxis against meningococcal and *H. influenzae* type b disease, in combination for mycobacterial disease and severe staphylococcal infections.

METRONIDAZOLE

It is active at low redox potentials producing toxic metabolites which damage DNA. The spectrum of activity is against anaerobic bacteria and protozoal organisms such as *Giardia* sp. Metronidazole is well absorbed orally and penetrates tissues and crosses the blood-brain barrier. Dizziness and a metallic taste can be present and peripheral neuropathy and encephalopathy can occur with long-term treatment. It is used for the treatment of and prophylaxis against infections that may include anaerobic bacteria, such as abdominal sepsis, and some protozoal infections, for example giardiasis.

Inhibitors of bacterial protein synthesis

TETRACYCLINES

They bind to the 30s ribosomal subunit and inhibit binding of the transfer RNA to the 30s ribosome. Activity is in Gram-positive bacteria including *S. aureus* and pneumococci, and some of the Gram-negative organisms

such as *H. influenzae* and gonococci. They have some anaerobic activity and are effective against the atypical bacteria, such as chlamydiae, mycoplasmas, rickettsiae and spirochaetes, and have limited protozoal activity. Tetracyclines are absorbed well orally but the different formulations vary in their half-life, so that doxycycline can be given once daily. They are well distributed in tissues but do not penetrate the CSF and should be used with caution in renal and liver failure. The commonest side effect is gastrointestinal intolerance, but photosensitivity reactions can be troublesome. Tetracyclines cannot be used in childhood or pregnancy because they are concentrated in developing bones and teeth. Owing to these side effects they are not used as first-line treatment of infections apart from rickettsial infections.

CHLORAMPHENICOL

It inhibits protein synthesis by binding to the 50s ribosome, is absorbed well orally, widely distributed in tissues and crosses the blood-brain barrier. Active in Gram-positive and -negative aerobic bacteria and many anaerobic bacteria, mycoplasmas, spirochaetes and rickettsiae. It is bacteriostatic against most microorganisms which limits its use but bactericidal against *H. influenzae* and *Neisseria* sp. The main adverse effect is 'grey-baby' syndrome in neonates due to a lack of hepatic enzyme activity with build-up of unconjugated chloramphenicol, resulting in circulatory collapse. In adults there is reversible dose-dependent bone marrow suppression, but 1 in 40,000 patients develop an irreversible aplastic anaemia. Potential toxic effects have limited its use, so that in the UK it is mainly used topically for ophthalmic infections.

MACROLIDES, FOR EXAMPLE ERYTHROMYCIN AND CLARITHROMYCIN

They inhibit the binding of tRNA to the 50s ribosome. The spectrum of activity is in Gram-positive organisms, *Neisseria* sp., *Haemophilus* sp., *Bordetella* sp. and some Gram-negative anaerobes. They are also active against *Mycoplasmas*, *Rickettsiae* and *Legionella* sp. Absorbed well orally, the newer macrolides such as clarithromycin have better pharmacokinetics with a longer half-life and azithromycin is concentrated intracellularly. Important adverse effects include nausea and vomiting as they increase gastric motility, and the intravenous preparations are associated with thrombophlebitis. Macrolides are an alternative therapy for respiratory infections if atypical organism or penicillin allergy is likely and an alternative treatment for chlamydial and campylobacter infections.

FUSIDIC ACID

Fusidic acid inhibits the translocation step of protein synthesis, and is mainly active against *S. aureus*.

Resistance emerges rapidly during treatment unless a second agent is given. It is absorbed well orally with good tissue penetration including brain abscesses, but does not reach the CSF. Generally it is well tolerated but cholestasis and jaundice can develop during therapy but this is much more common if the intravenous formulation is used. Clinical use is in severe staphylococcal infections, particularly bone and joint infections in combination with another anti-staphylococcal agent, and some superficial staphylococcal infections, such as impetigo, but resistance is increasing.

AMINOGLYCOSIDES

Aminoglycosides inhibit bacterial protein synthesis by binding to both subunits of the ribosome, resulting in misreading of the genetic code. They are active in Gram-negative bacilli, *S. aureus*, mycobacteria and *Brucella*, but there is no anaerobic activity and only synergistic activity against streptococci in combination with β -lactam agents. They are not absorbed orally, and therefore have to be given parenterally, and have reduced activity at a low pH. Ototoxicity, nephrotoxicity and neuromuscular paralysis are important side effects, with variations in the degree of toxicity between the different agents with neomycin being the most toxic. Therapeutic monitoring is mandatory because of their narrow therapeutic window and dose is adjusted according to age, renal function and weight. They are used to treat severe Gram-negative and staphylococcal sepsis, in combination with β -lactam agents in endocarditis and streptomycin is used as a second-line treatment for mycobacterial infections and brucellosis.

STREPTOGRAMINS

A combination of compounds binds to the 50s ribosome and cooperate to inhibit protein synthesis. Gram-positive activity includes some multiresistant enterococci, with additional activity against *Mycoplasma* sp., *Chlamydia* sp. and *Legionella* sp. Thrombophlebitis is an important adverse effect and usage is mainly limited to the treatment of resistant Gram-positive infections.

OXAZOLIDINONES, FOR EXAMPLE LINEZOLID

These are a new class of agents, which act on the bacterial ribosome, and display bacteriostatic Gram-positive activity, particularly against resistant staphylococci such as MRSA and vancomycin-resistant enterococci (VRE). Resistance has already been described. They are well absorbed orally. Thrombocytopenia is an adverse effect with prolonged therapy. They may be used as an alternative therapy for resistant Gram-positive infections such as VRE.

Antiviral agents

The scope of antiviral therapy is rapidly expanding as we understand the mechanism of antiviral replication. The need for antiviral agents has increased with the use of immunosuppressive therapies and the emergence of human immunodeficiency virus (HIV) infection. As RNA viruses, for example HIV, have a highly variable genome, drug-resistant mutants are readily produced, which is a particular problem when resistance is encoded by a single mutation event. Thus, combination therapy as with the treatment of tuberculosis (TB) is warranted for some viral infections.

AMANTADINE

Cell penetration of the virus and viral uncoating is inhibited. The spectrum of activity is in influenza A, but resistance can occur when it is used prophylactically. It is well absorbed orally, but central nervous system side effects reduce its use in the elderly. Clinically it is used for both the prophylaxis and treatment of influenza A. With the introduction of the newer agents active against the influenza viruses, usage is likely to be limited in the future.

NUCLEOSIDE ANALOGUES, FOR EXAMPLE ACICLOVIR, VALCICLOVIR, FAMCICLOVIR AND GANCICLOVIR

Chemical analogues of the natural purine or pyrimidine nucleosides, they are only active once they have phosphorylated within the host cell and then interact with the viral DNA or RNA polymerase, becoming incorporated in the nucleotide chain and distorting it or terminating further elongation. Aciclovir, valciclovir and famciclovir are active against herpes simplex virus types 1 and 2 and herpes zoster virus. Resistant mutants can be produced but as they are of low pathogenicity they rarely produce a clinical problem. Ganciclovir is more active against cytomegalovirus (CMV), which has a different thymidine kinase. Aciclovir can be given orally with 15–20 percent bioavailability and is widely distributed including the CSF, and is excreted renally so doses must be reduced in renal impairment. Valciclovir is an ester of aciclovir and famciclovir an ester of penciclovir with increased bioavailability, both of which can be used orally. Ganciclovir is poorly absorbed orally and only given intravenously. Among adverse effects are neurotoxicity with toxic levels of aciclovir and bone marrow toxicity with ganciclovir. Aciclovir is used to treat severe herpes simplex and zoster infections, i.e. encephalitis and ganciclovir for severe life-threatening CMV infections.

OTHER ANTIVIRAL DRUGS

Zanamivir and oseltamivir

They inhibit neuraminidase of influenza A and B viruses, thereby inhibiting their release from cells and reducing

disease and infectivity. Studies of the inhaled formulation have demonstrated a reduction in the duration of symptoms if used within 48 hours of onset. They are active in influenza A and B viruses. Zanamivir is given locally by inhalation which can precipitate bronchospasm. In the UK both are licensed for the treatment of influenza-like disease in at-risk adults who present within 48 hours of onset, and oseltamivir is also licensed for the treatment of at-risk children and for post-exposure prophylaxis in at-risk adults and adolescents over 13 years of age, when influenza is circulating in the community. Further studies of this and similar agents are awaited.

ANTIRETROVIRAL THERAPY

The introduction of highly active antiretroviral therapy has transformed the treatment of HIV infection, with dramatic sustained reductions in viral load and opportunistic infections. They fall into three main classes.

Nucleoside reverse transcriptase inhibitors, for example zidovudine and lamivudine

They are nucleoside analogues that inhibit reverse transcriptase thereby inhibiting the conversion from RNA to a DNA copy, and are active in HIV and lamivudine is also active against hepatitis B virus. Zidovudine is well absorbed orally and crosses the placenta and blood–brain barrier, and the main side effects are anaemia and neutropenia in the first six weeks of therapy. They are the mainstay of antiretroviral therapy and are used in combination to inhibit emergence of resistant strains.

Non-nucleoside reverse transcriptase inhibitors

These agents also inhibit the reverse transcriptase enzyme, but resistance emerges quickly on monotherapy, so that they can only be used in combination.

Protease inhibitors

Protease inhibitors include the antiretroviral agents indinavir, zidovudine and saquinavir which have activity against HIV. Some also have activity against enteroviruses, hepatitis C and rhinoviruses and are under investigation. They produce the greatest fall in HIV viral load but can cause significant toxicity, for example renal stones and lipodystrophy.

Antifungal therapy

Systemic fungal infections are an increasing problem with the emergence of resistant *Candida* sp. and the increased incidence of infections due to invasive moulds. Many antifungal therapies exist but a large number are toxic and therefore can only be used topically. Development of newer antifungal agents, such as the echinocandins, which

target the fungal cell wall more specifically, are promising. Antifungal resistance can be either primary, i.e. the organism is resistant prior to treatment, secondary, i.e. develops after exposure to antifungals, or clinical resistance, i.e. progression of the fungal infection despite treatment to which the organism is sensitive. Clinical resistance is particularly seen in profoundly immunosuppressed patients or where there is infected prosthetic material. Sensitivity testing of fungi is difficult to carry out and reproduce and does not always correlate with the clinical response. The main classes of systemic and topical antifungals are discussed below.

POLYENES

Polyenes, for example amphotericin and nystatin, bind to the sterols of eukaryotic cell membranes, causing leakage of cell contents, most can only be used topically as they can act on mammalian cell walls. Amphotericin B is active against nearly all fungi which produce human disease, and in addition, is active against *Leishmania* sp. Development of resistance has only rarely been described. Amphotericin is given parenterally for systemic infection as it is not absorbed orally and, as it is highly protein bound, and therefore enters the CSF poorly. Adverse effects include the infusion-related side effects of fever, rigors and headaches which can be reduced with the co-administration of steroids, also renal toxicity and hyperkalaemia. The incidence of serious side effects has been reduced by the incorporation of the amphotericin B into liposomes or other lipid carriers. This allows higher doses to be given with fewer toxic reactions. Nystatin is only used topically for yeast infections, whereas amphotericin is mainly used parenterally for severe invasive yeast infections, aspergillosis and other mould infections.

AZOLES

The azoles are the largest group of antifungal agents, inhibiting cytochrome P450 14 α -demethylase that is required for fungal cell wall synthesis. They are active in *Candida* sp., dermatophytes, with some activity against *Aspergillus* sp.

Imidazoles

The topical imidazoles, such as clotrimazole are powerful agents against oral, vaginal and skin candidiasis and dermatophytes infections. The oral formulation of the imidazole ketoconazole is generally more toxic than the triazoles, as 1 in 15,000 patients develop hepatitis.

Triazoles

Fluconazole has activity against most *Candida* sp. and *Cryptococcus* sp., but no activity against invasive moulds. Primary resistance is common with some non-albicans *Candida* sp., particularly *Candida krusei* and *Candida*

glabrata.⁴ Itraconazole and variconazole have improved activity over invasive moulds including *Aspergillus* sp. and *Fusarium* sp., but not the zygomycetes.

ECHINOCANDINS, FOR EXAMPLE CAPSOFUNGIN

Echinocandins are a new class of antifungals, which inhibit cell-wall glucan synthesis, leading to fungal cell lysis. Rapidly fungicidal against *Candida* sp., including azole-resistant species, they are active against *Aspergillus* sp., but not other moulds or *Cryptococcus* sp.

ALLYLAMINES, FOR EXAMPLE TERBINAFINE

Allylamines reduce ergosterol synthesis. The spectrum of activity is in dermatophytes, with poor intrinsic activity against yeasts and moulds, and are used in extensive skin and nail dermatophyte infections.

Other antifungal agents

FLUCYTOSINE

Flucytosine incorporates into fungal mRNA in the place of uracil, causing disruption to protein synthesis and DNA synthesis. Activity is in *Candida* sp. and *Cryptococcus* sp. only. Resistance is a common problem arising during treatment. Levels should be monitored and the dose reduced in renal failure. Important adverse effects are bone marrow toxicity and hepatotoxicity. It is used in combination therapy for severe candidal and cryptococcal infections such as meningitis.

GRISEOFULVIN

Griseofluvin is used to treat nail infections as it has restricted activity against dermatophytes but the mechanism of action is unclear.

ANTIMICROBIAL RESISTANCE

In the UK, the prevalence of resistant Gram-positive isolates is increasing, with 1.5 percent in 1990 and 3.9 percent in 1995 of pneumococcal isolates demonstrating low-level penicillin resistance, and 2.8 percent in 1990 and 8.6 percent in 1995 macrolide resistance.⁵ [**] In Eastern Europe, Spain and the USA the rates of penicillin and macrolides resistance in pneumococci are even higher.⁶ [**] There has also been an increase in glycopeptide-resistant enterococci. Although new agents with Gram-positive activity are being developed there is no reason to believe that resistance to these agents will not emerge.⁷ [**]

In addition, the number of multiresistant Gram-negative organisms, resistant to all the main Gram-negative antimicrobials are becoming an increasing problem in hospitals, and multidrug-resistant TB isolates have resulted in failures of TB treatment.

Antimicrobial resistance is not new, as some organisms are inherently resistant to antimicrobial agents either due to differences in the cellular target of the antimicrobial agent or inactivation of the antimicrobial. These mechanisms can be acquired by other organisms either by genetic mutation and selection of the resistant clone or acquisition of the genetic material required to produce the resistance in the form of plasmids, transposons or naked DNA. In the presence of antimicrobial selection pressure, organisms able to produce resistance determinants will be favoured. Unfortunately, some strains possess multiple resistance determinants which are more difficult to control as any of the antimicrobials can exert a positive selective pressure, for example MRSA strains currently circulating are resistant to all the β -lactam agents, quinolones and can be resistant to the macrolide antibiotics.

Antimicrobial sensitivity testing

An organism is defined as sensitive to an antimicrobial if the antimicrobial is active at concentrations that can be achieved therapeutically. The minimum inhibitory concentration (MIC) is the lowest concentration of the antimicrobial agent at which growth of the test organism is completely inhibited, whereas the minimal bactericidal concentration is the lowest concentration of the antimicrobial agent which achieves 99.9 percent killing of the test organism. Bactericidal activity is particularly important if infection is in a difficult site, such as a vegetation in endocarditis or in immunocompromised patients, where the additional effects of phagocytosis and antibody-dependent killing cannot be achieved. Agents that only achieve bacterial inhibition of replication are known as bacteriostatic agents.

Sensitivity testing can be performed by a number of methods. In a routine diagnostic laboratory determination of the MIC is time-consuming and too cumbersome to be carried out routinely. More rapid indirect methods are used which allow a number of organisms to be tested against a range of antimicrobials. A common method is the Stokes method, in which known concentrations of the antibiotic are impregnated into a disc that is released into the agar onto which the test organism and a control organism have been inoculated (**Figure 19.2**). The zone of inhibition of growth is compared with the known test organism after overnight incubation. The breakpoint method is used to test multiple organisms that are inoculated onto different agar plates containing high and low concentrations of a range of antimicrobials (**Figure 19.3**).

© Hodder Arnold / Scott-Brown 7E

Figure 19.2 Antimicrobial sensitivity testing of *S. aureus* against penicillin (P 1.5) using the modified Stokes method, demonstrating penicillin resistance in the test organism (top) and penicillin sensitivity in the control organism (bottom).

© Hodder Arnold / Scott-Brown 7E

Figure 19.3 Breakpoint sensitivity testing of multiple staphylococcal isolates against penicillin at a concentration of 0.1 mg/L. Growth of organisms at that concentration demonstrates penicillin resistance and where there is no growth there is penicillin sensitivity.

For more slow-growing organisms antimicrobial sensitivity testing can be slow, difficult to reproduce and technically difficult. Newer molecular methods have been developed for some of the slow-growing organisms where the genetic basis for the resistance is known, such as polymerase chain reaction to detect the rifampicin resistance gene in *Mycobacterium tuberculosis* isolates.

Laboratory sensitivity testing measures the activity of a known concentration of the pure drug against an organism growing exponentially in an artificial culture, which does not reflect the situation at the site of an active infection. Results should therefore be used as a guide to likely active antimicrobial therapy.

The main mechanisms of antimicrobial resistance are described below.

Antimicrobial-inactivating enzymes

Some organisms naturally produce enzymes that will inactivate antimicrobial agents, for example the β -lactamases, with over 95 percent of *S. aureus* isolates resistant due to the production of this enzyme. Other β -lactamases are able to break down the β -lactam bond of the cephalosporins and have been acquired by Gram-negative organisms. Enzymes can also inactivate the aminoglycosides.

Altered antimicrobial binding site

The action of an antimicrobial can be reduced or inhibited by alterations in the cellular target. Penicillin resistance in pneumococci results from an alteration in the affinity of the penicillin-binding protein, with production of a cell wall that will not bind penicillin, the genetic mechanism for which has been acquired from commensal oral streptococci. Resistance to the sulphonamides and trimethoprim can occur due to alterations in the target enzymes in the folate synthesis pathway. Many viruses develop resistance to antiviral agents by point mutations in the genes which encode the antiviral target protein, for example HIV resistance to lamivudine.

Altered antimicrobial penetration

Alteration of the bacterial outer cell membrane may prevent penetration of a particular class of antimicrobials into the cell, for example in *Pseudomonas aeruginosa*. Bacteria may also become resistant by rapid removal of the antimicrobial from the cell before it is able to act, as seen with the tetracyclines.

ADVERSE EFFECTS OF ANTIMICROBIAL AGENTS

The basic principle of antimicrobial chemotherapy is selective toxicity, i.e. killing of the microorganism with no toxic effects to the patient. Most antimicrobial agents have a wide therapeutic window. Adverse events are either dose dependent, such as renal toxicity of aminoglycosides,

or idiosyncratic reactions, such as anaphylaxis with penicillins.

Cutaneous adverse effects

These vary from fixed drug eruptions, photosensitivity rashes through to life-threatening Stevens-Johnson syndrome. The sulphonamides are well known to be a common cause of these cutaneous reactions. Mild itchy rashes are common with penicillins and cephalosporins. Anaphylaxis occurs if the antimicrobial agent initiates a type I hypersensitivity reaction; this is an uncommon event that occurs in about 1 in 100,000 treatments.

Haematological effects

Bone marrow toxicity can result from the normal action of the drug, an idiosyncratic reaction or immune mechanisms. Irreversible aplastic anaemia is an uncommon but serious idiosyncratic side effect of chloramphenicol therapy. Metabolic bone marrow suppression can occur in agents which affect nucleic acid synthesis, such as the antivirals zidovudine and ganciclovir, or those which reduce folate synthesis, such as the sulphonamides. Reversible granulocytopenia alone can also occur with the sulphonamides and with prolonged high doses of the penicillins and cephalosporins usually after two to three weeks of high-dose therapy. Occasionally, antibiotics can induce the production of antibodies to red cells or platelets, producing Coombs' positive haemolytic anaemia, such as with rifampicin or immune thrombocytopenia.

Liver toxicity

Damage to the liver can be acute or chronic hepatitis, cholestasis, fatty degeneration or granulomatous hepatitis. Hepatocellular damage is the commonest form of damage to the liver, most often seen with the antituberculous agents rifampicin and isoniazid, which in combination cause hepatitis in about 5 percent of cases. Granulomatous hepatitis is a rare side effect of high-dose ampicillin and flucloxacillin therapy and after prolonged quinine therapy. Cholestatic jaundice is most commonly seen with fusidic acid therapy particularly with doses above 2 g/day and with the intravenous preparation.

Gastrointestinal side effects

Antimicrobials similar to other drugs can produce nausea, vomiting and diarrhoea, but with antimicrobial agents, diarrhoea can be caused by the alteration of the colonic microflora and the overgrowth of toxin producing

C. difficile. *Clostridium difficile* infection can result in a spectrum of disease from asymptomatic carriage or mild diarrhoea through to severe diarrhoea with pseudomembranous colitis. Although most antibiotics have been associated with a predisposition to *C. difficile* infection, the most commonly implicated agents have been clindamycin, cephalosporins and ampicillin.⁸ [**] More recently, the quinolone antibiotics have also been implicated.

Renal toxicity

Renal damage can happen for a number of reasons during therapy. Direct renal cell damage or nephrotoxicity can occur with a number of antimicrobials, particularly the aminoglycosides and amphotericin. The aminoglycosides are toxic to the cells of the proximal renal tubules at serum levels close to the levels required to produce an antimicrobial effect, i.e. there is a narrow therapeutic index. This toxicity is more likely to arise in the elderly and those with pre-existing renal impairment and treatment with other potentially nephrotoxic agents. They can also be ototoxic leading to impaired hearing and vestibular damage. To prevent this happening therapy must be closely monitored and doses adjusted according to age, weight and renal function. Renal toxicity is commonly seen with amphotericin therapy, which has led to the production of liposomal formulations that are less nephrotoxic.

KEY POINTS

- The pace of development of antibiotic resistance has become faster than the development of new antibacterial agents.
- Antibiotic resistance is threatening the effective treatment of infections both in the community and hospital.
- Novel new antifungal and antiviral therapies are under development.

Best clinical practice

- ✓ The decision to use antimicrobials should be with knowledge of the likely causative organism(s), antimicrobial sensitivity, site of infection, spectrum of activity of the antimicrobial and the risks of treatment and of untreated infection.
- ✓ Use antibiotics for surgical prophylaxis where there is proven benefit.
- ✓ Do not give repeated or prolonged courses of antimicrobials without evidence of benefit.

- ✓ Try and use narrow-spectrum agents where adequate cover for the likely organism(s) is achieved.
- ✓ Follow your local antimicrobial guidelines and liaise with your local microbiologist for difficult infections, as rates of resistant organisms vary from area to area.

SEARCH STRATEGY

The information and data in this chapter were produced from a Medline search using the key words otolaryngology, HIV, AIDS, otology, occupational exposure and lymphoma.

INTRODUCTION

Human immunodeficiency virus (HIV) and the acquired immunodeficiency syndrome (AIDS) has had a profound effect on the practice of medicine in the 20 years since its discovery. Initially a disease of homosexual men and haemophiliacs, it is now a disease that affects individuals of every age, sex and socioeconomic group, becoming a worldwide epidemic and spreading into regions of the globe such as Southeast Asia. There are over one million HIV-positive people in China alone, and the number is steadily growing. Women form an increasing subset of patients and with this comes vertical transmission of the virus from mother to child. Head and neck manifestations of the disease are prevalent, and up to 100 percent of HIV patients will have some head and neck presentation of the disease during the course of their illness.

HUMAN IMMUNODEFICIENCY VIRUS

HIV is an example of a **retrovirus**, a virus whose genetic material is present in the form of ribonucleic acid (RNA)

Two copies of identical

instead of DNA. Its genetic material is a diploid, **single-stranded RNA** that uses the enzyme reverse transcriptase to convert its ssRNA into double-stranded DNA. The HIV has a **lipid bilayer membrane** for an outer cell envelope that is acquired from the host cell from which it was produced. This envelope contains two glycoproteins, **(gp)41 and gp120**, which form a complex essential for cell proliferation. The gp120 glycoprotein binds to the **CD4 receptor on the host-cell membrane**. CD4 receptor is found in highest concentrations in T helper lymphocytes, and it is through these cells that HIV primarily proliferates. CD4 receptors are also found in lesser numbers in monocytes/macrophages. Once gp120 and the CD4 receptor are bound, the viral and host-cell membranes fuse. This allows the viral contents to be injected into the host cell. Reverse transcriptase then catalyzes the synthesis of viral DNA from RNA. The viral DNA then migrates into the host-cell nucleus and integrates itself into the host DNA. Once incorporated, the viral DNA is replicated along with the host cell DNA and passed onto progeny cells. The provirus, once activated, begins to synthesize new virus particles (RNA, reverse transcriptase and other enzymes) using host cell

transcription machinery. These particles assemble beneath the host-cell membrane and then bud through, thus acquiring their own membrane from the host. The host cell is subsequently destroyed during this process and the viral particles infect new CD4-positive cells. As helper T lymphocytes are the primary cells infected, their destruction is what primarily causes immunodeficiency in the host. Cells of the monocyte/macrophage lineage have also been shown to express CD4 and thus can be infected by HIV and act as reservoirs.^{1,2}

Once initial infection occurs there is often a clinical latency period of approximately six to ten years, during which time there may be no symptoms. During this latency period, viral replication and CD4⁺ lymphocyte destruction continues. As the CD4⁺ count decreases, the patient's clinical course worsens. In 1986, the Centers for Disease Control (CDC), together with the World Health Organization, attempted to establish a staging system for AIDS which used clinical criteria to stage disease progression. A second staging system by the CDC followed which classified the different stages of HIV infection from asymptomatic to full-blown disease.³ The Walter Reed Staging Classification was developed in 1986, dividing HIV infection into six stages and including analysis of CD4 counts. The absolute T helper lymphocyte count is still currently used to measure disease progression.

Upon initial infection with HIV, the patient may be asymptomatic. However, 50–70 percent of people will have an acute illness within two to six weeks of infection consisting of acute onset of fever, mucocutaneous ulceration, maculopapular rash and pharyngitis. This syndrome lasts about two weeks. These patients may be seronegative, but have high titres of virus in the bloodstream and are highly infectious. Viral loads decrease as serum antibody to HIV increases, and by six months most patients are seropositive. Patients at this stage are generally asymptomatic. Circulating CD4 counts are generally high during this period, which may last for years. Once the CD4 counts start to decrease, symptomatology may resume beginning with fatigue and generalized lymphadenopathy. Further decreases in CD4 count produce more constitutional symptoms including fever, sweats, chills, weight loss, night sweats and diarrhoea. With further declines, the patient becomes susceptible to more opportunistic infections and neoplasms, some of which (e.g. *Pneumocystis carinii* pneumonia) are essentially diagnostic for AIDS.

THERAPY

Currently, there is no vaccine or cure for infection with HIV, which is universally fatal. However, with further elucidation not only of the life cycle of the virus but the progression of infection, various agents have been created which have helped to extend the life of HIV-infected individuals. Secondary treatment for HIV includes

symptomatic treatment of opportunistic infections. Primary treatment consists of a variety of drugs that inhibit viral progression at different stages of its life cycle.

One of the earliest classes of drugs created was the nucleoside analogues, one of the first being 3'-azido-2'-deoxythymidine zidovudine (AZT). This class of drugs acts as an antimetabolite by becoming phosphorylated and binding to and inhibiting reverse transcriptase. The benefits of this class of drugs are limited by the emergence of viral resistance. Toxicity of this class of drugs includes fatigue, nausea, headache, macrocytic anaemia and neutropenia.

Another class of antiretroviral drugs is the non-nucleoside analogues. Nevirapine and delavirdine are two agents in this class.^{2,4} The major side effect of these drugs is a rash.

The protease inhibitors are a class of drugs that act by inhibiting the protease used to cleave polypeptides in the budding virion into their functional form, thus halting viral maturation. Drugs in this class include saquinavir, ritonavir, indinavir and nelfinavir. Toxicities are variable among the different drugs. Saquinavir has the least side effects (diarrhoea, nausea, abdominal discomfort), but also has the least efficacy and bioavailability. Ritonavir is on the opposite side of the spectrum with high efficacy but also more side effects including more severe gastrointestinal side effects and elevations in liver function tests and triglycerides.

OCCUPATIONAL EXPOSURE

Physician exposure to HIV-infected individuals will continue to rise as the prevalence of HIV infection increases. Many of these encounters will occur without the physician or the patient having any knowledge of infection. Of HIV-infected patients 70–80 percent will have some manifestation necessitating evaluation by an otolaryngologist. Very few seroconversions have occurred despite numerous job-related exposures to body fluid contaminated with HIV. The risk of contracting HIV after a single hollow needlestick injury is 0.36–0.5 percent if the incident involves blood known to have the HIV virus.⁵ Sticks involving solid needles, metal wires and scalpels have a lower risk. Universal Blood and Body Precautions was issued by the CDC in 1987, and was an attempt to set out standards that can be used by all healthcare providers to decrease the risk of HIV exposure. The basis of these precautions is that every patient should be seen as potentially HIV positive, and protective measures instituted. The use of latex gloves and double gloving, to decrease risk of exposure from puncture injury, has been advocated. There were specific recommendations for handling sharp instruments as they are involved in most accidental stick injuries. Needle stick injuries are a common source of injury, and therefore needles should never be recapped. In the operating theatre or the office,

avoidance of direct hand-to-hand passage can be avoided by using a magnetic pad, kidney basin or Mayo stand. Using staples during wound closure instead of sutures also decreases the risk of inadvertent stick injury. Protective eye wear and gowns should always be worn in the operating theatre and are even recommended in some office encounters where the risk of encountering contaminated secretions is high.

In cases where the physician or healthcare worker is exposed to blood or bodily secretions, the area of skin or wound that was exposed should be immediately washed with soap and water. If the patient's HIV status is unknown, informed consent should be obtained for testing of the patient for HIV as well as hepatitis B and C. The involved healthcare worker should have a baseline HIV test performed, with subsequent tests at six weeks and three months.⁶ Chemoprophylaxis is recommended for workers sustaining puncture injuries or high-risk contact with contaminated body fluids and should be instituted within two hours after exposure. AZT is recommended for all prophylaxis regimens with the addition of a protease inhibitor for higher-risk exposures.

HEAD AND NECK MANIFESTATIONS

Otologic

EXTERNAL EAR

Seborrheic dermatitis and Kaposi's sarcoma (KS) are dermatologic lesions that can occur on the pinna and the external auditory canal (EAC). Seborrheic dermatitis can occur in the periauricular region and the EAC as well as the face and scalp. Applying a zinc pyrithione-containing shampoo over the affected area typically treats it. Other treatments include washing with coal tar, selenium sulphide or ketoconazole. A 1-percent hydrocortisone lotion may be used as adjunctive treatment in refractory cases. Seborrheic dermatitis often recurs and this fact should be included in patient education. Kaposi's sarcoma has an incidence higher in the AIDS population than the general population. When the pinna or external auditory canal is involved, a conductive hearing loss may manifest secondary to obstruction. Treatment of KS will be further detailed under dermatologic manifestations.

Staphylococcus aureus is the usual bacteria involved when there is a cellulitis of the pinna, and usually resolves with either oral antibiotics or i.v. antibiotics in more severe cases. Otitis externa is a severe infection of the external auditory canal most frequently caused by *Pseudomonas aeruginosa*. Symptoms include severe otalgia, otorrhoea and fever. Treatment involves topical antibiotics and/or 2-percent acetic acid and steroid drops in addition to canal debridement as often as is necessary. If severe swelling occurs, a wick should be placed in the EAC to maintain patency and further direct topical drops.

In HIV and/or diabetic patients in whom the above measures do not result in improvement, osteomyelitis of the skull base should be suspected. Other warning symptoms include facial nerve or cranial nerve dysfunction. Diagnosis can be confirmed using a computed tomography (CT) scan of the temporal bone or technetium 99m-bone scan. Treatment is six weeks of antibiotics. Coverage should be broad spectrum and include coverage against *P. aeruginosa*.⁷ [**] Surgical debridement may be necessary in more severe cases. *Aspergillus fumigata* can also present as a chronic otitis externa. In severely immunocompromised individuals, *Aspergillus* infection can become invasive with subsequent skull base and intracranial extension.

Any subcutaneous cyst or polyp in the EAC should be biopsied. *Pneumocystis carinii* may present as either a cyst or polyp, and the cyst if allowed to grow can occlude the EAC.² The diagnosis is made by biopsy and staining with Gomori's methenamine silver stain, and treatment with trimethoprim/sulphamethoxazole usually results in resolution of infection. *Mycobacterium tuberculosis* can also present as a polyp in the external auditory canal.

MIDDLE EAR

The most common otologic entities seen in HIV-positive individuals are serous and recurrent otitis media. Pathogenic organisms involved include *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis*. *Pseudomonas* and *Staphylococcus* organisms have been isolated more commonly from the AIDS population than the general population. There is a variety of aetiologies that includes Eustachian tube dysfunction, nasopharyngeal neoplasms, adenoid hypertrophy and sinusitis/allergies. Nasopharyngeal neoplasms should be ruled out in HIV-infected individuals, particularly with unilateral otitis media. Myringotomy and tympanostomy tube placement can offer symptomatic relief easily and quickly. Treatment of associated sinusitis or allergies should also be instituted. Adenoidectomy is indicated when more conservative measures fail.

Mastoiditis in the AIDS population is usually caused by *S. pneumoniae*. Its incidence does not appear to be increased in the AIDS population versus the general population. Antibiotic therapy directed towards the pathogens most commonly responsible for otitis media is usually sufficient treatment, although there have been reported cases of atypical organisms causing mastoiditis such as *A. fumigata*.⁸ Intravenous antibiotics and surgical drainage is indicated for coalescing suppurative mastoiditis.

INNER EAR

Individuals with HIV and AIDS can have a high rate of otologic symptoms referable to the inner ear. They can present with aural fullness, vertigo, tinnitus and sensorineural hearing loss. These symptoms can be caused by the

virus itself which can affect the central nervous system or CN VIII; or can be a side effect of the many medications that these patients often take. Many of the opportunistic infections that this population is prone to can cause sensorineural hearing loss, infections such as cytomegalovirus (CMV), herpes simplex virus (HSV) and herpes zoster virus. Cytomegalovirus, although well documented as a cause of congenital deafness, has not been directly implicated in adult onset hearing loss. It has been shown in temporal bone autopsy studies to have infected the inner ear in approximately 20 percent of those bones studied. Some of the ototoxic medications that these patients take include acyclovir, gancyclovir, AZT and isoniazid. Ootosyphilis can present at any stage of HIV infection, and HIV infection can hasten development of otosyphilis in the latent stage of the disease. Diagnosis is primarily by clinical history with confirmatory serologic studies (fluorescent treponemal antibody absorption test. Symptoms primarily consist of low frequency hearing loss, labyrinthine symptoms and aural fullness may or may not be present.⁹ Treatment is with high-dose penicillin and steroids. In AIDS patients, long-term steroid use should be avoided and it is suggested that any patient in a high-risk population who presents with sudden onset unilateral or bilateral hearing loss be tested for HIV prior to institution of steroid therapy. Steroid use may be contraindicated if there is concomitant opportunistic infection.

The work-up for hearing loss by the otolaryngologist in an HIV-infected individual with hearing loss should include an audiogram, auditory brain stem response and serologic treponemal testing. Imaging with CT is appropriate when neurologic findings are found on neurologic examination.

Facial nerve palsy can occur in up to 7.2 percent of HIV patients and is referable to direct infection by the HIV, neoplasms, opportunistic infections, AIDS encephalopathy and toxoplasmosis. Bell's palsy is the most frequent diagnosis given for CN VII paralysis. It is postulated to be caused by HSV and is a diagnosis of exclusion. Complete recovery usually occurs within three weeks to three months.^{2,10} Ramsay Hunt syndrome (herpes zoster oticus) usually occurs later in HIV infection and is more prevalent in AIDS patients. Symptoms include peripheral facial nerve palsy, herpetic vesicles along the seventh nerve dermatome and in the conchal bowl, and severe herpetic pain. The aetiology of this syndrome is varicella zoster virus infection of the geniculate ganglion. The diagnosis is clinical, and evaluation should include an audiogram and electrophysiological tests. Treatment is with high-dose acyclovir and high-dose steroids when not contraindicated.

NOSE AND PARANASAL SINUS

Thirty to sixty-eight percent of HIV-positive patients will manifest some form of nasal and/or sinus symptom.¹¹

Nasal obstruction secondary to a variety of aetiologies is a complaint that commonly causes these patients to see an otolaryngologist. Adenoidal hypertrophy can present as nasal obstruction, as can hypertrophy of any of the tissues in Waldeyer's ring. Any nonpediatric patient with adenoid hypertrophy should be tested for HIV. The obstruction caused by lymphoid hyperplasia can lead to a variety of other aetiologies including otitis media with effusion and upper airway obstruction. As with any nonimmunocompromised adult, unilateral otitis media with effusion warrants a thorough nasopharyngeal examination. Treatment should start with medical therapy that consists of topical steroid sprays and antibiotics. Surgical measures include adenoidectomy and a pressure equalization tube placement in refractory cases.

Neoplasms such as KS or non-Hodgkin's lymphoma (NHL) can also cause nasal obstruction.¹² Both lesions can arise from the nasal cavity or nasopharynx. Kaposi's sarcoma can also arise from the nasal septum. Non-Hodgkin's lymphoma can also arise from the sinuses.

Sinusitis in HIV-positive individuals is similar in symptomatology to that in noninfected persons. Symptoms include purulent nasal discharge, facial pain, headache and congestion. In HIV-positive persons with fever of unknown origin, the sinuses should always be investigated for possible infection. The bacteria involved in sinusitis include *S. pneumoniae*, *M. catarrhalis* and *H. influenzae* and are similar to that of nonimmunocompromised patients. In chronic sinusitis, *S. aureus* and anaerobic bacteria become more common. As the CD4 count decreases below 50/ μ L, fungal infection of the sinuses can occur (Figure 20.1), with the majority of fungal infections the result of *Aspergillus*.¹³ Other pathogens reported in the literature include CMV,¹⁴

Figure 20.1 In advanced HIV disease, invasive fungal infection of the paranasal sinuses must be considered. As seen in this axial CT scan, subtle bony erosion with extension into the infratemporal fossa (arrow) indicates an invasive fungal process.

Microsporidia,¹⁵ *Acanthamoeba castellanii*¹⁶ and *Legionella pneumophila*.

Evaluation of sinusitis in HIV-positive patients is similar to that of HIV-negative patients. Nasal endoscopy can be performed in the office, and the physician should not only look for signs of sinusitis (purulent discharge), but also evaluate the nose and posterior choanae for adenoid hypertrophy, nasal masses/neoplasms, destructive lesions, etc. In addition, endoscopy is simple to perform and can be used to follow the patient's response to management. Imaging should be performed by CT scan, which gives superior visualization of all the sinuses, particularly the sphenoid sinuses and posterior ethmoids.

The hallmarks of medical management of sinusitis are antibiotics and decongestants. Oral antibiotics should be instituted for three to four weeks. First-line antibiotics include amoxicillin, Augmentin (amoxicillin/clavulanate), cephalosporins and Bactrim (sulphamethoxazole/trimethoprim). Augmentin and the cephalosporins offer more broad-spectrum coverage. During the three to four week period of antibiotics, decongestants should also be part of the medical therapy. Systemic decongestants, such as pseudoephedrine, are recommended but their use may be limited in patients with underlying hypertension or cardiac problems. Topical decongestants such as oxymetazoline may be used, but their use should be limited to three to five days secondary to possible rebound congestion upon cessation of use. Topical nasal steroids may also be considered as an adjunctive therapy. There is also evidence suggesting a role for quiafensin therapy for these patients.¹⁷

The bacteriology of chronic sinusitis differs from that of acute sinusitis. In patients with CD4 counts $< 200/\mu\text{L}$, *S. aureus*, *P. aeruginosa* and anaerobes become more prominent, and antibiotic therapy should be broadened to include these organisms. Cultures should be obtained to confirm the bacteriology and further direct treatment. Antibiotics should be instituted for up to six weeks.¹⁸

Surgery is advocated in patients with persistent symptoms despite medical therapy, or in any patient at any time with extra-sinus symptoms (mental status changes, cranial nerve dysfunction, intracranial extension, abscess, etc.). Endoscopic sinus surgery is particularly effective. It can be performed as an outpatient procedure, and has low morbidity. The goal of surgery should be symptomatic relief, as well as optimizing nasal anatomy to facilitate drainage of the sinuses. However, as HIV disease progression continues and CD4 counts decrease, the physician can expect recurrent sinus infections that become more difficult to treat.

ORAL CAVITY

Oral cavity manifestations of AIDS are extremely common and can occur in up to 100 percent of AIDS patients. Recurrent aphthous ulcers are common in

immunocompromised patients, are generally larger than those in nonimmunocompromised patients and can vary in size from 1 mm to 4 cm. On physical examination, the lesions are solitary or multiple appearing, have an erythematous halo that is well circumscribed, and may have an exudate or pseudomembrane. The lesions are tender to palpation, and in giant aphthous ulcers can cause severe odynophagia and pain. In severe cases, the pain may accentuate the anorexia and dehydration that can be seen in AIDS patients. Treatment is primarily to provide symptomatic relief. Topical anesthetics or steroids are often effective in less severe cases. Miles' mixture (liquid tetracycline, hydrocortisone and viscous lidocaine in Orabase with nystatin) is a combination of various topical agents that is often effective. Topical tetracycline has also been shown to be an effective analgesic agent. Topical tetracycline or systemic clindamycin are effective agents when superimposed infection is present.

An intralesional steroid injection with triamcinolone acetonide has been shown to have analgesic effects within 24–48 hours after injection, and has very few side effects.¹⁹ [**] Oral thalidomide has been shown in some studies to heal ulcers completely in 55 percent of patients and partially in 90 percent of patients, but is only recommended to be used for two to four weeks at a time secondary to increased production of HIV and tumour necrosis factor- α .²⁰ [**] Thalidomide also has teratogenic effects limiting its use in women, who comprise an increasing number of AIDS patients.

Oral candidiasis is an infection that presents as a tender white plaque atop an erythematous and erosive mucosal surface. In some forms, the lesions can be removed with scraping, leaving a friable, bleeding base. In the chronic hypertrophic form, the plaques are heaped up and not easily removed with scraping. As with recurrent aphthous ulcers, the lesions can be extremely painful, leading to malnutrition, dehydration and wasting if not effectively treated. Treatment in patients who are not severely immunocompromised consists of Nystatin solution that is swished around the mouth and swallowed. Clotrimazole troches are also effective. Systemic therapy is indicated in patients with worsening immunocompromise or thrush unresponsive to topical agents. Ketoconazole or fluconazole are two agents frequently used. Severe cases require amphotericin administered intravenously.

Hairy leukoplakia is unique to HIV-positive individuals and typically arises on the lateral border of the tongue as a white, raised, corrugated or filiform lesion. It can also arise on the dorsal tongue, buccal and labial mucosa, floor of mouth or soft palate. It requires no treatment and is usually asymptomatic.

Oral herpes simplex commonly presents as herpes labialis (fever blisters, cold sores), the most common manifestation of infection in HIV patients. The lesions frequently present as small bullae that form ulcerations after they rupture. These lesions are painful and in HIV

patients, generally larger than in immunocompetent individuals. Treatment consists of oral acyclovir.

Gingivitis in HIV patients tends to be more severe than in noninfected patients. It can easily progress to a necrotizing gingivitis or severe periodontal disease. Gingivitis presents as erythema of the gum line with inflammation and interdental soft tissue papillae edema. Bleeding from the gums can occur with seemingly light or no trauma. Periodontitis presents as loosening of periodontal attachments. It can progress to acute necrotizing ulcerative gingivitis which is an ulcerative process along the gingival margin leading to destruction of the periodontal soft tissues. Treatment consists of antibiotics aimed at anaerobic organisms and topical irrigations with chlorhexidine gluconate. If available, a referral to a dentist or oral surgeon should be made early in the process.²¹

Human papilloma virus can present as a verrucous, flat or spiky lesion in the oral cavity. It appears similar to venereal warts and usually appears in synchrony with anal or genital lesions. While often solitary lesions, these can occur as widespread involvement of the entire oral cavity and oropharyngeal mucosa (Figure 20.2). Treatment consists of surgical excision, but recurrence is likely.

Xerostomia secondary to chronic inflammation of the major and minor salivary glands is frequently seen in HIV patients. As with xerostomia from other causes, the development of dental caries and periodontal disease is a major concern. Also, nutritional deficiencies secondary to impaired deglutition can occur. The treatment is for symptomatic relief and consists of oral irrigations, saline rinses, salivary substitutes and sialogogues.²²

Kaposi's sarcoma is the most common HIV-related oral malignancy, with the majority arising on the palate. This tumour can also appear on the gingival

(Figure 20.3) or oropharynx. Diagnosis is by either excisional or punch biopsy. Treatment is necessary only for lesions that cause functional impairment or for cosmesis with enlarging lesions. There is a variety of therapeutic options. Intraleisional vinblastine injection has been shown to be effective in bringing about regression by inducing local fibrosis.²³ [**] Sodium tetradecyl sulphate works in a similar manner and has also been shown to be effective. Kaposi's sarcoma has been shown to respond well to radiation, however its side effects include mucositis and can exacerbate existing xerostomia.²⁴ Surgical excision using a laser is helpful in debulking larger lesions.

Non-Hodgkin's lymphoma may also arise in the oral cavity. In AIDS patients, NHL is usually a poor prognostic indicator of disease progression. Recurrences are common despite chemotherapy and radiation. The lesions may present as an ulcerative lesions, but typically appear red and exophytic. They usually involve the gingiva and alveolar ridges and may arise from Waldeyer's ring.²⁵

Table 20.1 reviews the characteristics and treatment of many of the most common oral manifestations of HIV disease.

PHARYNX AND LARYNX

Many of the same processes that affect the oral cavity can also affect the larynx and pharynx. Many of these processes present with similar symptoms: odynophagia, dysphagia and in some cases, chest pain. Correctly identifying and treating these processes can not only provide symptomatic relief, but in many cases, also help in dealing with the wasting and malnutrition that can occur.

Barium swallow and oesophagoscopy should be performed if the diagnosis of oesophageal candidiasis is

© Hodder Arnold / Scott-Brown 7E

Figure 20.2 While often presenting as solitary lesions, oral papillomas can be widespread covering much of the oral and oropharyngeal mucosa. This patient has multiple papillomas of the dorsal tongue, which predictably recurred following surgical management.

© Hodder Arnold / Scott-Brown 7E

Figure 20.3 The gingival is a common site for presentation of Kaposi's sarcoma.

Table 20.1 Characteristics and treatment of the most common oral manifestations of HIV.

Disease		Management	Comment
Gingival disease	Can develop gingival tissue loss, tooth loosening/loss, bone exposure	Best treatment is frequent dental cleanings, flossing, etc. Aggressive antibiotics and/or surgical management when advanced	Common in HIV Requires close dental evaluations and frequent management
Oral thrush	Pseudomembranous candidiasis: Typical plaque-like lesions Atrophic form with erythematous lesions on palate, buccal mucosa, tongue Angular cheilitis	Topical agents such as clotrimazole Systemic agents (e.g. fluconazole) for refractory cases in patients with advanced disease	Prolonged or frequent use of fluconazole increases risk of azole-resistance candidiasis
Oral aphthous ulcers	Lesions may be large Biopsy confirms non-neoplastic, nonviral aetiology	Topical steroid therapy Intralesional or systemic steroids Thalidomide Antiretroviral therapy	Are usually difficult to treat Produce severe pain, odynophagia Often cause substantial morbidity
Kaposi's sarcoma	Typically on hard, soft palate Occasionally on gingival, buccal mucosa	Symptomatic relief When functionally problematic, low-dose radiotherapy or intralesional vinblastine or systemic chemotherapy	
Radiation mucositis	Side effect of treatment for other oral lesions	Topical therapy (steroids, antifungals, etc.) Supportive care – nutrition, pain management, hydration	Can result even from low doses of radiation
Hairy leukoplakia	Usually occurs on side of tongue Probably Epstein-Barr virus related	No treatment necessary if asymptomatic	Must be differentiated from other more serious oral disorders

suspected. Symptoms include retrosternal pain, odynophagia and/or dysphagia. Barium swallow will show an irregular surface to the mucosa secondary to ulcerations and candidal lesions. Direct visualization and biopsy can be obtained with oesophagoscopy. Treatment is with systemic amphotericin B or fluconazole. Laryngeal candidiasis presents as hoarseness and, in severe cases, stridor or shortness of breath. Fiberoptic laryngoscopy confirms the diagnosis along with biopsy. Again, treatment is with systemic antifungal agents.

Herpes simplex viral infection in the pharynx or larynx can present with similar symptoms as oesophageal and laryngeal candidiasis. Examination reveals discrete vesicles with mucosal ulceration. Biopsy and viral culture of lesions confirm diagnosis.

Kaposi's sarcoma can present primarily in the pharynx and/or larynx or extend to adjacent areas including the oral cavity. Orophageal KS may present with dysphagia secondary to obstruction or haematemesis secondary bleeding from the lesion. Laryngeal lesions may present as shortness of breath, hoarseness or severe airway compromise. Such lesions are treated aggressively. First, the airway should be secured. In acute settings of airway compromise, intubation and/or tracheostomy should be considered. Treatment, unlike with oral cavity lesions, is

typically radiation. Intralesional vinblastine has been shown to yield a complete response in certain lesions of the upper aerodigestive tract.²⁶

OESOPHAGUS

Oesophageal inflammatory diseases are commonly seen in advanced HIV disease. The most common causes of these conditions are oesophageal candidiasis, herpetic oesophagitis, CMV infection and aphthous ulceration.

Oesophageal candidiasis is the most common, accounting for over 50 percent of the cases of oesophagitis in this population.²⁷ Although it can occur as an isolated infection, it is usually associated with oropharyngeal thrush. This association is so common that patients with oesophageal symptoms, also presenting with oral thrush, can be treated empirically for candida oesophagitis.²⁸ The symptoms of candidiasis consist of dysphagia (a feeling of difficulty in swallowing), odynophagia (pain when swallowing) and occasionally substernal chest pain. While the diagnosis occasionally requires endoscopy, empiric treatment can usually be instituted using a systemic antifungal agent, such as fluconazole for up to two weeks, especially in the setting of significant oropharyngeal

thrush. If a clinical response is not noted early in the treatment regimen, then an alternative diagnosis should be considered, and also endoscopy.²⁹ [**]

Cytomegalovirus is the second most common infectious ulcerative condition of the oesophagus. Of patients who fail empirical antifungal therapy, approximately one-third will have CMV ulcerations.^{30, 31} These ulcers tend to occur more commonly in the distal oesophagus with a raised indurated border and necrotic base. While occasionally occurring as solitary ulcers, CMV can also form multiple or diffuse ulcerations and lacking any defined pathognomonic appearance.³¹ Unfortunately, other than biopsy and culture, there are also no disease-specific clinical characteristics that differentiate this from other forms of ulcerative oesophagitis. Once the diagnosis has been established, treatment can be instituted using intravenous gancyclovir or foscarnet.

Herpes simplex virus is a much less common cause of HIV-related oesophagitis (5 percent in some studies).³¹ The symptoms are similar to those of other oesophageal diseases; however, on gastrointestinal endoscopy the ulcerative lesions tend to be smaller and sometimes confluent. The occurrence of HSV is usually associated with significant immune dysfunction, usually occurring only when the CD4 level is well below 100/mm³.³² Treatment usually starts with intravenous acyclovir followed by oral agents.

Idiopathic oesophageal ulcer arises with the same frequency as CMV oesophagitis, and although its aetiology is unclear, there is usually no associated specific infectious aetiology. These lesions also usually occur with severe immunocompromise. The endoscopic appearance is similar to CMV lesions, often with solitary, large ulcerations with raised indurated margins. Treatment has been effective using systemic steroids.³³ Recent success has also been described with thalidomide, although this agent is currently not widely available.³⁴ [**]

SALIVARY GLANDS

Both major and minor salivary glands can be involved in disease processes in the HIV-infected individual. The most common complaint is xerostomia. The parotid gland, in particular, may be involved in some disease processes secondary to intraglandular lymph node involvement. The differential diagnosis for a person with parotid gland enlargement must include infection and salivary gland neoplasm (HIV-associated as well as the standard salivary gland neoplasms).

Included in the differential is the lymphoepithelial cyst, a disease process that is almost diagnostic of HIV infection as it was extremely rare prior to the AIDS era.³⁵ Lymphoepithelial cysts present as a parotid swelling, unilateral or bilateral, which progresses over months and is generally nontender (Figures 20.4 and 20.5). Facial nerve dysfunction should lead the physician to suspect a

© Hedder Arnold / Scott-Brown 7E

Figure 20.4 The most common etiology of an asymptomatic parotid mass in the HIV-infected patient is the lymphoepithelial cyst (arrow).

Figure 20.5 This axial CT scan demonstrates the typical findings (arrow) of a benign parotid lymphoepithelial cyst.

malignant neoplasm. Fine-needle aspiration reveals fluid with lymphocytes and squamous epithelial cells. Computed tomography imaging will show multiple thin-walled cysts in the parotid gland. With fine-needle aspiration biopsy (FNAB) and imaging, open biopsies or surgical excision for diagnosis is rarely indicated. Lymphoepithelial cysts are usually benign, and surgery is

only necessary for enlarged lesions that are a cosmetic challenge or where the diagnosis is equivocal. Needle aspiration of cyst contents is ineffective for long-term cure as recurrence almost always happens.³⁶ [**] However, it is effective as a temporary treatment and for diagnostic purposes. Radiation therapy has shown some efficacy although, as when used to treat KS, it can cause severe mucositis locally. Superficial parotidectomy is the only permanent treatment and carries its own share of potential morbidities including damage to the facial nerve.

NECK

The majority of HIV patients may present with a neck mass at some point during their illness. In this population, the differential diagnosis includes four categories of disease process: neoplasm, infectious, HIV lymphadenopathy and parotid disease.

Neoplasms that can present as neck mass include KS, NHL and squamous cell carcinoma. Kaposi's sarcoma is one of the disease processes that define AIDS. Prior to the AIDS epidemic, it was mostly encountered on the lower extremities of people of Mediterranean or Ashkenazi Jewish descent. During the AIDS epidemic, its incidence increased in the male homosexual and bisexual population. With increasing spread via intravenous drug use and the increasing incidence in women worldwide, this distribution may change. The risk of KS increases with CD4 counts $<100/\mu\text{L}$ and tends to be more aggressive. Lesions can occur as cervical lymphadenopathy in the neck, skin, oral cavity and lungs. In the neck, diagnosis can be made by FNAB or open biopsy.

Non-Hodgkin's lymphoma is more aggressive in immunocompromised patients and is the second most common neoplasm in HIV patients. It can present as a neck mass that is rapidly enlarging and usually nontender. Although it can present as nodal mass, NHL localized to the neck is uncommon in HIV-infected patients and systemic disease is the norm. Extranodal presentations are also more common in HIV-infected patients (Figure 20.6). Constitutional symptoms (fever, night sweats and weight loss) usually occur with disease. Diagnosis is normally made by open biopsy with subsequent immunohistochemical staining and evaluation of cell architecture.

Hodgkin's disease can also present as a painless, enlarging neck mass in HIV patients. At the time of presentation, most patients have disseminated disease. As with NHL, Hodgkin's disease can be difficult to manage in HIV patients.

There have been reported cases of squamous cell carcinoma presenting as a cervical mass in AIDS patients. Evaluation is similar to that of cancer of unknown primary in non-HIV patients. Treatment is usually surgical.

Figure 20.6 This patient presented with a non-Hodgkin's lymphoma of the right cheek. Extranodal presentations are common in patients with HIV disease.

Infectious processes that can cause neck masses in HIV-positive patients are numerous. There are a few that deserve special mention, as misdiagnosis of them can ultimately prove fatal in immunocompromised patients. Toxoplasmosis is a condition caused by the organism *Toxoplasma gondii*, a protozoan which infects humans who ingest tissue cysts contained in the meat of certain animals. In immunocompetent patients, symptoms include a self-limiting course of constitutional symptoms and cervical lymphadenopathy. In immunocompromised patients, toxoplasmic encephalitis can result in a central nervous system space-occupying lesion that is usually bilateral. Computed tomography scans of the head are useful for identifying these lesions. Definitive diagnosis is by biopsy and tissue culture; however, tissue culture ultimately takes anywhere from six days to several months. Therapy should be started presumptively based on history and CT scan. Treatment consists of pyrimethamine and sulphadiazine for six weeks.

Pneumocystis carinii is the most common opportunistic pathogen in AIDS patients. It is an opportunistic organism that only becomes pathogenic in immunocompromised individuals. Primarily it causes a pneumonia that presents as a progressive consolidation of the lungs. *Pneumocystis* prophylaxis is widely instituted in HIV patients, leading to more extrapulmonary manifestations. Since it is primarily a pulmonary process, any person with an extrapulmonary manifestation of *P. carinii* should have a pulmonary work-up. Head and neck manifestations include a lymphadenitis or a thyroiditis. Fine-needle aspiration biopsy specimens should be examined using the Gomori methenamine-silver stain that stains the cyst form of the organism, and histopathologic examination. Cervical infections respond to dapsone, trimethoprim/sulphamethoxazole or pentamidine.

Extrapulmonary *M. tuberculosis* infection in an HIV patient can present as an enlarging neck mass. It is usually

firm, nontender, has a rubbery consistency, and may present with a draining sinus tract. Cervical lymphadenopathy may be the only symptom of tuberculous infection, therefore tuberculosis should always be on the differential diagnosis for neck masses. HIV-positive patients have a higher rate of reactivation of latent disease than their immunocompetent counterparts. Diagnosis is via administration of the purified protein derivative skin test. In immunocompetent individuals, a 10-mm reaction is considered positive. This criterion is lowered to 5 mm in immunocompromised individuals. Controls to test for anergy should also be placed. Positive results may also be seen with nontuberculous mycobacterial infections.

Nontuberculous mycobacterial infections, particularly *Mycobacterium avium* complex (MAC), are the most common mycobacterial infections seen in HIV patients, whereas in their immunocompetent counterparts, *M. tuberculosis* is more common. MAC infection, in the later stages of AIDS, presents as disseminated infection. Therefore, MAC infection of cervical lymph nodes should lead to a thorough investigation for disseminated infection. Treatment is with ciprofloxacin and clofazimine, as MAC is resistant to standard antimycobacterial medications.

Fungal infections may also manifest as a cervical mass. Rarely do they present as isolated cervical lymphadenopathy. Disseminated infection should be suspected in patients with fungal lymphadenopathy. Treatment is usually with amphotericin B, and lifelong suppressive therapy is necessary following successful treatment. In HIV-infected patients, *Cryptococcus neoformans* is the most prevalent form of infection. Cryptococcal meningitis is the most frequent presentation of cryptococcosis in HIV patients. Cultures for fungus should be obtained with all neck node biopsies.

Human immunodeficiency virus lymphadenopathy (also called persistent generalized lymphadenopathy) can arise early in HIV infection, often within months of initial seroconversion. The syndrome is defined as two or more extrainguinal sites of lymphadenopathy which last for more than three months and have no obvious source. Lymphadenopathy in the head and neck region can occur anywhere, but particularly in the posterior triangle, periauricular areas and submental and submandibular lymph nodes. Routine biopsy (fine-needle or excisional) is not recommended.

The work-up for a neck mass in an HIV-positive patient begins with a thorough history and physical including questions about time of onset, duration and possible precipitating events. Any constitutional symptoms, or lack thereof, should be well documented. A thorough review of systems, focusing particularly on pulmonary and central nervous system symptoms, should be obtained. The patient's recent travel history should be ascertained. There should be a thorough physical examination, detailing not only the cervical lesion in question, but also any other oral cavity or nasal lesions.

Computed tomography or magnetic resonance imaging should be obtained to evaluate the size of the lesion, location and composition. Fine-needle aspiration biopsy can be used to obtain a tissue sample and perhaps guide therapy. Criteria exist for determining whether to perform open biopsy of a suspicious lymph node. Biopsy is indicated in individuals with a single lymph node >3 cm in patients with HIV lymphadenopathy, localized/enlarging/unilateral lymphadenopathy, constitutional symptoms, cytopenia/elevated erythrocyte sedimentation rate, or substantial mediastinal or abdominal lymphadenopathy.³⁷ Using these criteria, the physician can decrease the likelihood of biopsy morbidity in the patient, decrease the risk to the surgeon and medical personnel, and decrease the likelihood of the results returning as simple HIV lymphadenopathy.

DERMATOLOGIC

Seborrheic dermatitis is a common inflammatory disorder seen in HIV patients. It may present as scaly patches over the scalp. Treatment is with steroid creams and shampoos (see under Otologic above).

Herpes simplex virus can present as large ulcers on the face that are extremely tender. Ulcerative lesions in AIDS patients are presumed to be HSV until proven otherwise. Herpes simplex virus infection lasting more than one month is an indicator of AIDS. Diagnosis is made by Tzanck smear, viral cultures, skin biopsy or fluorescent antibody staining of scrapings from lesions.

Herpes zoster may present in immunocompromised patients secondary to reactivation of latent virus. It presents as vesicular lesions that appear over a particular dermatome. There can be severe pain during and after acute episodes. Ramsay Hunt syndrome can occur with facial nerve involvement and there may be ocular complications with involvement of the trigeminal nerve. The diagnosis is clinical, however Tzanck smear can be used for confirmation. Episodes are usually self-limited. Treatment of simple cases consists of oral acyclovir, which helps to shorten the course. Disseminated cases, Ramsay Hunt syndrome or ophthalmic involvement should be treated with intravenous acyclovir.

Molluscum contagiosum is a skin lesion caused by a poxvirus, which presents as a pearly, umbilicated papule, in approximately 10–20 percent of AIDS patients. Treatment is with curettage. Retinoic acid applied topically may assist in decreasing the size and rate of appearance of new lesions.

Bacillary angiomatosis is caused by infection with Gram-negative bacteria related to the organism that causes trench fever, and occurs with immunosuppression. It can present in a variety of different ways, most frequently as a bright red, papular lesion that is friable. It may also present as a cellulitic plaque or a subcutaneous nodule. It can occur in skin or viscera. Diagnosis is by

biopsy and is identified with the Warthin-Starry stain. Since visceral lesions can also arise, investigation of suspicious skin lesions is imperative. Treatment is with erythromycin for skin manifestations.

Staphylococcus aureus infection can present on the skin as a folliculitis, furuncle, carbuncle or abscess. The nares is the most common site of colonization. In HIV-positive homosexual men, the carriage rate is double that of noninfected homosexual men.³⁸ It is the most common cause of cutaneous bacterial infection in HIV infection. Infection typically occurs through breaks in skin secondary to needle sticks and indwelling venous catheters. Infection is precipitated in general by neutropenia secondary to bone marrow suppression from medications, and defective chemotaxis of neutrophils secondary to HIV infection. Treatment is with oral anti-staphylococcal antibiotics and incision and drainage of abscesses.

Kaposi's sarcoma is a malignant tumour of endothelial cell origin and is the most common AIDS-associated neoplasm. In the head and neck region, it can affect any cutaneous surface as well as upper aerodigestive tract mucosa. Skin lesions are painful and appear as purple or brown skin nodules varying in diameter size from 1 mm to 2 cm. Smaller lesions may coalesce to form large lesions. The diagnosis is made by appearance and biopsy. Histologic appearance is variable and may resemble a simple haemangioma with haemosiderin-laden macrophages and tightly packed capillaries. Although vascular in appearance, bleeding is not considered a risk of biopsy. Treatment options include intralesional vinblastine, carbon dioxide laser excision, cryotherapy and low-dose radiation.

KEY POINTS

- One hundred percent of HIV patients will present head and neck manifestations at some point during the course of their illness.
- Lymphoepithelial cyst in the parotid is virtually diagnostic of AIDS.
- Oral hair leukoplakia is a benign process which must be distinguished from other more serious oral conditions.
- *Candida oesophagitis* is the most common aetiology of serious oesophageal inflammatory conditions; however, when empiric therapy is ineffective, oesophagoscopy with biopsy may be necessary to direct therapy.
- Sensorineural hearing loss in AIDS patients can be multifactorial and include the neurotropic effects of the HIV virus, ototoxic medications used to treat HIV and opportunistic infections.

- Otitis media with effusion in HIV patients warrants an evaluation of the nasopharynx to rule out a nasopharyngeal mass.
- Any nonpediatric patient with adenoid hypertrophy should be tested for HIV.
- Kaposi's sarcoma is a malignant tumour with increased incidence in HIV-positive individuals versus the general population. It can present at a variety of sites including the ear, nose, face and oral cavity.
- The differential diagnosis for a neck mass in HIV patients is vast and includes HIV lymphadenopathy, infectious, neoplastic and parotid disease. Specific recommendations exist for when biopsy of a neck node should be performed.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words transfusion, components, blood sparing agents, alternative, adverse events.

INTRODUCTION

Widely available and practised worldwide, the transfusion of blood and its constituent components has played a major role in allowing significant advances through greater medical and surgical intervention. However, the scientific basis of transfusion and the complications which can follow transfusion are not always used to make an informed decision to transfuse patients. This chapter reviews the biology of the major blood groups, the constituents of blood and their indications, the problems encountered when transfusion causes adverse effects and potential alternatives to blood transfusion.

HUMAN BLOOD GROUPS AND THEIR CLINICAL SIGNIFICANCE

There are 23 human blood group systems, leading to a huge variety of red cell phenotypes. The most important of these is the ABO system.

ABO blood groups

Patients are grouped by serological testing into either group O, A, B or AB. Patients of all groups have a common H antigen on the red cell membrane surface, which is coded for by the H gene on chromosome 19. This H antigen may then be acted upon by further enzymes, depending on the presence of ABO genes on chromosome 9. Each person inherits two ABO genes. The O gene is nonfunctional so that if an individual has not inherited either the A or B gene, then the H antigen alone is detected on the red cell surface. Such individuals are Group O. However, if an individual has inherited an A or B gene then each codes for a specific enzyme which adds a specific sugar to the H gene product producing either the A, B or AB phenotype (Table 21.1). People form antibodies to any of the ABO antigens that they lack. These antibodies appear during the first few months of life due to the exposure to ABH-like antigens in the environment. The ABO system is significant because these antibodies are of the immunoglobulin (Ig)M type and thus are capable of

Table 21.1 ABO blood groups.

Blood group	Frequency in UK population (%)	Genotype	Red cell antigens	Antibodies in plasma
O	47	OO	Nil	Anti-A, anti-B
A	42	AO AA	A	Anti-B
B	8	BO BB	B	Anti-A
AB	3	AB	A and B	Nil

Table 21.2 Rh D blood group.

Blood group	Frequency in UK population (%)	Genotype	Antigens	Antibody
Rh D-positive	85	DD or Dd	D	–
Rh D-negative	15	dd	Nil	Anti-D after first exposure

D gene is dominant, codes for D antigen; d gene is recessive, codes for no antigen.

complete activation of complement through to red cell lysis. Therefore, if the wrong (mismatched) blood is transfused into a patient, a potentially fatal reaction may ensue.

The Rh blood group system

The Rh system (originally termed ‘Rhesus’ system, when discovered in Rhesus monkeys) is a complex system of 45 antigens encoded on chromosome 1. The most important is the Rh D antigen, which is highly immunogenic and 90 percent of individuals exposed to Rh D-positive blood by transfusion will produce anti-D antibodies, which are of IgG type (Table 21.2).

Rh D-negative women may also become sensitized and form anti-D by an Rh D-positive foetus at times when fetomaternal haemorrhage occurs, e.g. at delivery. Anti-D is important as it can not only cause a delayed haemolytic transfusion reaction if Rh D-positive blood is transfused, but anti-D antibodies can also cross the placenta. Therefore, if a Rh D-negative woman has anti-D and she carries a Rh D-positive baby, anti-D may attach to the foetal red cells and cause haemolysis. This may cause either haemolytic disease of the newborn or even death of the foetus due to hydrops fetalis.

Therefore, a Rh D-negative woman of childbearing age must always receive Rh D-negative blood.

Other blood group systems

It is impossible to provide ‘identical’ or fully matched red cells for transfusion. In practice, ABO and Rh D identical

blood is provided and in addition, all patients are tested to determine if they have any antibodies to other clinically significant red cell antigens – if so, antigen negative blood must be provided to prevent a delayed haemolytic transfusion reaction from occurring. Red cell antibodies occur in 3.8 percent of patients. For some antibodies, antigen negative blood may need to be obtained from a regional blood centre. Therefore, a patient is tested before each transfusion episode to screen for the presence of antibodies, i.e. a group and screen (G&S) test, by incubating the patient’s plasma with two different fully antigen typed ‘screening’ red cells which are known to possess all the blood group antigens which matter clinically. If the antibody screen is negative, any blood which is ABO- and Rh D-compatible could be given. If the antibody screen is positive, the antibody(ies) must be identified using a large panel of red cells of known antigen types. As antibodies can develop 2 days to 20 weeks after a transfusion episode, a new blood sample is required for antibody screening if the patient has been transfused recently. [***] [Grade C/D].

Crossmatch

The patient’s plasma is incubated with the donor red cells from units of blood selected for transfusion to double check that the patient has no antibodies present which could react with antigens on the donor’s red cells to cause a delayed haemolytic transfusion reaction. Blood is normally reserved for a particular patient for 48 hours.

Maximum surgical blood ordering schedule

For some elective surgical procedures, blood may only rarely be used so to crossmatch blood for all patients undergoing such a procedure would be a waste of staff time, reagents and blood may be reserved for sequential patients and expire without being used. Therefore, for operations where blood is used in less than a third of procedures, if a patient's group and screen test shows no antibodies are present, a crossmatch is not performed. This is safe as in the event of an unexpected bleeding emergency, as no antibodies are present, ABO- and Rh D-compatible blood can be provided within 10 minutes. However, the corollary is that if a patient's group and screen does show an antibody, a full crossmatch must be done before surgery. A maximum surgical blood ordering schedule (MSBOS) is normally compiled by agreement between surgeons, anaesthetists and haematologists and is individually tailored to each hospital, taking into account the procedures performed, operators, logistical arrangements of the blood bank, etc. Table 21.3 shows an example. This only applies to elective and not emergency surgery and the blood provided can be altered on discussion, if there are clinical factors which make significant bleeding more likely, for example, if a patient has a coagulopathy. [Grade D]

TIMING OF GROUP AND SCREEN OR CROSSMATCH SAMPLES BEFORE ELECTIVE SURGERY

Routine samples are tested in batches, so normally, a G&S requires approximately half a working day to complete, but if the antibody screen is positive, an additional half a working day or more is required. Therefore a G&S or crossmatch sample should be sent 24 hours before surgery to ensure that blood can be provided if the patient has an antibody. It is usual for anaesthetists to check that any crossmatched blood requested is available before surgery is started, but the equally important check that results of a G&S are available so that blood could be provided during surgery if needed, is not commonplace. With ever-reducing time between patient admission and elective surgery, patients may have G&S or crossmatch samples taken instead at pre-assessment clinics several days or weeks before surgery. It is safe practice to perform a G&S test on these samples and freeze the plasma until a few days before surgery, then crossmatch blood if required

Table 21.3 Example of a surgical blood ordering schedule.

Procedure	Blood order
Tumour of palate	G&S
Laryngectomy	2 units
Radical neck dissection	2 units
Commando	4 units

using this sample, provided that the patient's doctor, has ensured that the patient had not been transfused in the six months prior to the sample being taken so that new red cell antibodies cannot develop between obtaining the sample and transfusing the patient. If a patient has been transfused, a new sample is required before transfusion can be given. [Grade C/D]

EMERGENCY SURGERY

In an emergency, a patient's blood group and antibody screening can be tested manually. A test for the patient's ABO and Rh D group takes approximately 10 minutes and an antibody screen takes approximately 30 minutes: the times taken for samples to be sent to the laboratory and for blood to be taken to the patient are not included. Figure 21.1 shows a typical example of what blood can be provided in an emergency. To avoid misunderstandings, communication between clinicians and laboratory staff to establish 'how long from now until blood is needed at the bedside' is crucial.

BLOOD COMPONENTS

Whole blood may be split into various components, to allow for efficient use of donated blood, as illustrated in Figure 21.2.

Red cell transfusions

Whole blood is rarely used in modern clinical practice: red cell concentrates, which have had plasma removed for other products, are used in preference. Each unit is estimated to raise the Hb concentration in an adult by 1 g/dL. Donated blood is collected into a pack containing the anticoagulant citrate phosphate dextrose (CPD) and then after centrifugation, transferred to a pack containing saline-adenine-glucose-mannitol (SAGM) medium suitable for optimal red cell storage. Red cells are then stored at 4°C for up to 35 days to minimize proliferation of any contaminant bacteria.

PREOPERATIVE PREPARATION

To avoid unnecessary transfusion, patients should be assessed well in advance of surgery so that simple measures can be taken, e.g. correction of iron deficiency anaemia and arrangements made for stopping nonsteroidal antiinflammatory drugs or anticoagulants, where appropriate.

INDICATIONS FOR TRANSFUSION

It is difficult to answer the question 'when should red cells be transfused'. Broadly, blood should be given when the

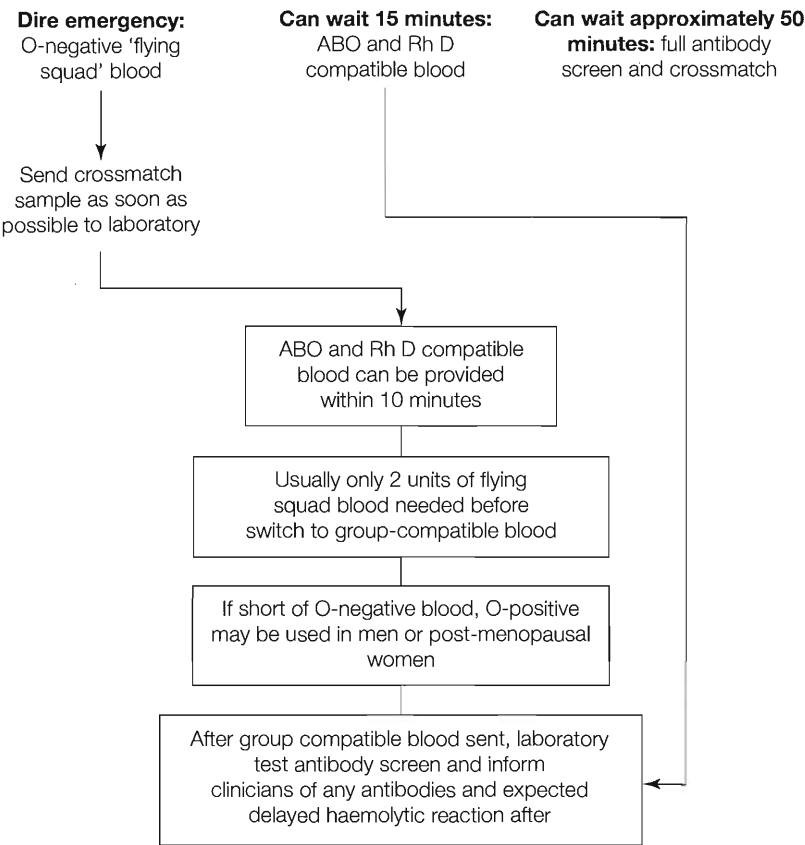

Figure 21.1 Provision of blood in an emergency.

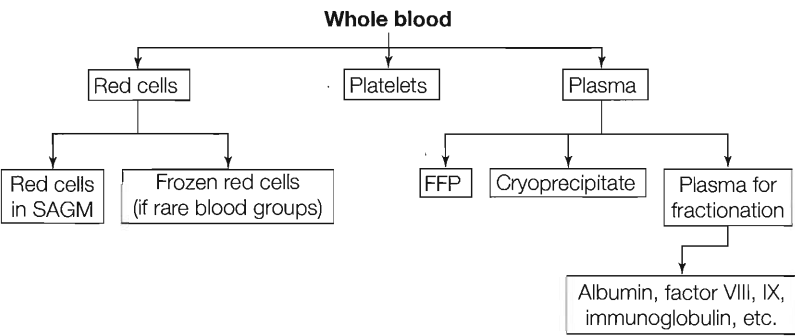

Figure 21.2 Blood components and products derived from whole blood.

potential benefits outweigh the risks. Most hospitals have policies addressing the use of blood and components, as agreed among surgeons and haematologists and based on national guidelines. The British Committee for Safety in Haematology guidelines, *The clinical use of red cell transfusion*, published in 2001, provides useful guidance on when to transfuse patients, as summarized below.¹ [Grade C/D]

British Committee for Safety in Haematology guidelines 2001

ACUTE BLOOD LOSS

Patients with acute massive loss should ideally be managed by experienced clinicians in a suitable setting.

A blood sample should be sent for the urgent provision of blood according to hospital policy.

As it is often difficult in such circumstances to estimate blood loss, the classification given in **Table 21.4** is a useful guide to measuring hypovolaemic shock. According to the British Committee for Safety in Haematology (BCSH) guidelines:¹

Requirement for transfusion based on an estimation of blood loss

- 15 percent loss of volume (750 mL in an adult or estimate the circulating blood volume by $75 \times \text{weight in kg}$): No need for blood transfusion unless blood loss is superimposed on pre-existing anaemia or when the patient is unable to compensate for this

Table 21.4 Clarification of hypovolaemic shock according to blood loss.²

	Class I	Class II	Class III	Class IV
<i>Blood loss</i>				
Percentage	< 15	15–30	30–40	> 40
Volume (mL)	750	800–1500	1500–2000	> 2000
<i>Blood pressure</i>				
Systolic	Unchanged	Normal	Reduced	Very low
Diastolic	Unchanged	Raised	Reduced	Very low unrecordable
Pulse (beats/min)	Slight tachycardia	100–120	120 (thready)	> 120 (very thready)
Capillary refill	Normal	Slow (> 2 s)	Slow (> 2 s)	Undetectable
Respiratory rate	Normal	Normal	Tachypnoea (> 20/min)	Tachypnoea (> 20/min)
Urinary flow rate (mL/h)	> 30	20–30	10–20	0–10
Extremities	Colour normal	Pale	Pale	Pale and cold
Complexion	Normal	Pale	Pale	Ashen
Mental state	Alert	Anxious or aggressive	Anxious, aggressive, or drowsy	Drowsy, confused, or unconscious

Reproduced with permission from the BMJ Publishing Group.

loss due to pre-existing cardiac or respiratory disease.

- 15–30 percent loss of volume (800–1500 mL in an adult): Need to transfuse crystalloids or colloids. The need for red cells is unlikely unless the patient has pre-existing anaemia, reduced cardiorespiratory reserve or if blood loss continues.
- 30–40 percent loss of blood volume (1500–2000 mL): Rapid volume replacement is required with crystalloid or synthetic colloids, and red cell transfusion will probably be required.
- 40 percent loss of blood volume (> 2000 mL) rapid volume replacement including red cells is required. [Grade D]

Requirements for red cell transfusion based on haemoglobin concentration

- Red cell transfusion is not indicated when estimates of actual and anticipated haemoglobin concentrations are >10 g/dL.
- Red cell transfusion is indicated when the rate of concentration is <7 g/dL. Red cells should be given in relation to ongoing red cell loss. If the patient is otherwise stable, two units of red cells should be transfused in adults (or the equivalent in children according to size) and then the clinical situation and haemoglobin concentration should be reassessed.
- The correct strategy for transfusion of patients with haemoglobin concentrations between 7 and 10 g/dL is less clear. Clinicians often transfuse red cells, although the available evidence suggests this is not often justified.
- In patients who may tolerate anaemia poorly, e.g. patients over the age of 65 and patients with cardiovascular disease, consider adopting a higher haemoglobin level at which transfusions are indicated.

These guidelines provide a framework for clinical transfusion, but the decision to transfuse should be based on the individual patient's circumstances. [Grade D]

A retrospective review of transfusion in sinus surgery in Germany found that 0.46 percent of patients needed a transfusion, but that blood loss and therefore the need for transfusion decreased when a combination of endonasal surgery and controlled intraoperative hypotension were used.³ Risk factors for requiring a transfusion were extensive polypsis and purulent exacerbation of sinus disease. A study in the United States concluded that transfusion is no longer necessary during routine bimaxillary orthognathic surgery⁴ and another study found that using hypotensive anaesthesia and consistent surgical techniques, 0.8 percent of patients required transfusion.⁵ Small patients requiring double-jaw procedures were the ones most likely to need blood. [Grade C/D]

Fresh frozen plasma

The use of fresh frozen plasma (FFP) in the UK has increased over many years, but there is evidence that it is often given unnecessarily.⁶ It is usual practice for requests for FFP, platelets and cryoprecipitate to be discussed with a haematologist.

CHARACTERISTICS OF FRESH FROZEN PLASMA

Plasma is separated from whole blood by centrifugation and frozen to -30°C within six hours of its collection (**Table 21.5**). Thawing of FFP takes about 30 minutes from the time of request and should be used within two hours for it to maintain its optimal clinical effectiveness. It cannot be refrozen for further storage.

FFP should be ABO-compatible to avoid a mild haemolytic reaction due to anti-A or anti-B in the FFP.

Table 21.5 Blood components.

	Storage (°C)	Shelf-life	Dose	Outcome measures
Red cells	4°C ± 2	35 days	1 unit	Rise Hb 1 g/dL in adult
Platelets	Room temp – keep agitated	5 days	1 pool	Rise in platelet count of approximately 40 and monitor bleeding
FFP	Frozen	1 year	12–15 mL/kg	Monitor APTT and PT and bleeding
Cryoprecipitate	Frozen	1 year	10 donor units (may be pooled)	Monitor fibrinogen level

FFP is not crossmatched, but the patient needs to have had a G&S test. A small amount of red cell contamination may be present in FFP so women of childbearing age should therefore receive Rh D-compatible FFP to prevent possible sensitization. In an emergency situation if Rh-positive FFP has to be issued to Rh D-negative women, i.m. anti-D can be administered to prevent immunization.

INDICATIONS FOR FRESH FROZEN PLASMA

National BCSH guidelines give recommendations for the use of FFP.⁷ [Grade C/D]

Definite

- thrombotic thrombocytopenic purpura (TTP);
- acute disseminated intravascular coagulation (DIC);
- immediate reversal of warfarin effect;
- replacement of single coagulation deficiencies where a specific or combined concentrate is unavailable;
- vitamin K deficiency;
- C1 esterase inhibitor deficiency.

Disseminated intravascular coagulation

Disseminated intravascular coagulation leads to deficiencies in coagulation factors particularly V, VIII and fibrinogen, and platelets. In patients who are actively bleeding and in whom laboratory tests indicate DIC, FFP, platelets and cryoprecipitate are often required. Subsequent therapy should be based on repeat coagulation tests and with the guidance of haematological colleagues. In chronic DIC or DIC without haemorrhage, there is no indication for FFP just to normalize laboratory results.

Vitamin K deficiency

Patients who present to surgical teams with biliary obstruction may have impaired absorption of the fat soluble vitamin K and therefore have a deficiency of vitamin K-dependent coagulation factors. If immediate correction is required, e.g. for haemorrhage or imminent surgery, FFP is indicated.

Reversal of warfarin effect

In an emergency, FFP (or prothrombin complex concentrate) can be used to reverse warfarin effects. In elective surgery, the risks of potential adverse effects of FFP must be balanced against the urgency of the surgery, and should be discussed with the patient, before deciding whether to reverse the effect of warfarin or postpone the elective surgery to allow the warfarin to be stopped ahead of surgery. Recommendations from the BCSH guidelines are summarized in **Table 21.6**.

Conditional use of fresh frozen plasma

In cases of massive transfusion (>5 L in 24 hours), dilution of clotting factors may occur. In patients who are hypotensive or septic, DIC may also complicate cases of massive transfusion. In most hospitals, the first dose of FFP (12–15 mL/kg) is given empirically, as laboratory coagulation results take at least 25 minutes to obtain, but subsequent use of FFP should be based on the results of repeated coagulation screens and guidance should be taken from a haematologist. Platelet and fibrinogen levels may also be required. The platelet count should be kept above $50 \times 10^9/L$. If the fibrinogen level is $<0.8 g/L$, cryoprecipitate should be given. ‘Formula replacement’, e.g. after a certain number of units of red cells is not proven to be of benefit, so is not indicated. [Grade B/C/D]

Liver disease

Patients who have liver disease may need FFP if they have bleeding associated with a coagulopathy. They may have significantly expanded plasma volumes (due to ascites and/or oedema) and the coagulopathy may be difficult to correct with FFP alone. If six to eight units of FFP fail to correct the coagulation tests in a bleeding patient prothrombin complex concentrate may be indicated, in spite of the associated increased risk of thrombosis. Such cases should be discussed with a haematologist. [Grade D]

No indication for fresh frozen plasma

Fresh frozen plasma is not indicated in the following:

- hypovolaemia;
- immunodeficiency;

Table 21.6 Reversal of warfarin anticoagulant effect.

Condition	Treatment
Life-threatening haemorrhage	Immediately give 5 mg vitamin K by slow intravenous infusion and a concentrate of factor II, IX, X (PCC) with factor VII concentrate if available The dose of concentrate should be calculated based on 50 IU factor IX/kg body weight. If no concentrate is available, FFP should be infused (15 mL/kg), but this may not be as effective
Less severe haemorrhage such as haematuria or epistaxis	Withhold warfarin for one or more days and consider giving vitamin K 0.5–2.0 mg i.v.
INR of > 4.5 without haemorrhage	Withdraw warfarin for 1 or 2 days then review
Unexpected bleeding at therapeutic levels	Investigate possibility of underlying cause such as unsuspected renal or alimentary tract disease

- nutritional support/protein loss states;
- plasma exchange procedures, unless there is an underlying coagulopathy.

CRYOPRECIPITATE

This is a product rich in factor VIII and fibrinogen and is made by thawing fresh frozen plasma overnight at 4–8°C. Indications for cryoprecipitate include treatment of DIC, where the fibrinogen is <1 g/L and in rare cases of fibrinogen deficiency.

PLATELETS

Platelet concentrates have made a major contribution to modern clinical practice, in particular in allowing the development of intensive treatment regimes for haematological and other malignancies.

Platelet collection and storage

Platelet concentrates are produced either by pooling platelets derived from four separate donations of whole blood or as single donor platelets which are obtained by apheresis.

For optimal platelet function, platelets, unlike red cells, are stored under conditions of gentle agitation (to prevent clumping) at a temperature of $22 \pm 2^\circ\text{C}$. However, the shelf-life is limited to five days because of the risk of bacterial proliferation at this storage temperature. Sepsis secondary to platelet transfusion is more common than red cell infusion and therefore platelets should only be used when necessary. In the ENT setting, if patients have mild oral haemorrhage, the antifibrinolytic agent tranexamic acid (see Chapter 23, Haemostasis: Normal physiology, disorders of haemostasis and thrombosis and their management) may be a valuable alternative either as tablets or as an effective mouthwash suspension.

Indications for platelet transfusion

The cause of thrombocytopenia should be established as soon as possible so that the most appropriate treatment can be given and so that platelets are not given in conditions where they could cause harm. Serious

spontaneous haemorrhage due to a low platelet count alone is unlikely to occur at platelet counts $> 10 \times 10^9/\text{L}$.⁸ BCSH guidelines suggest in stable thrombocytopenia, a threshold of $10 \times 10^9/\text{L}$ for platelet transfusion, in the absence of any additional risk factors, e.g. sepsis antibiotic use or other abnormalities of haemostasis.⁹

Recommendations for platelets as surgical prophylaxis

Recommendations for various surgical procedures are as follows: [Grade D]

The platelet count should be kept above $> 50 \times 10^9/\text{L}$ for:

- lumbar puncture;
- epidural anaesthesia;
- gastroscopy and biopsy;
- insertion of indwelling lines;
- transbronchial biopsy;
- liver biopsy;
- laparotomy or similar procedures.

For operations at critical sites such as the eye and brain, the platelet count should be kept $> 100 \times 10^9/\text{L}$.

Prior to a procedure, it is essential to repeat the platelet count after platelets have been transfused to ensure an adequate increment has been achieved.

Platelets may be required in massive transfusion or in acute DIC and in each the platelets should be kept $> 50 \times 10^9/\text{L}$. Again repeated platelet counts are invaluable in acting as a guide to therapy. In chronic DIC, platelet transfusion is not routinely given to correct the thrombocytopenia. [Grade D]

Contraindications to platelet transfusion

- Heparin-induced thrombocytopenia (HIT) (see Chapter 23, Haemostasis: Normal physiology, disorders of haemostasis and thrombosis and their management). In such cases, platelet transfusion has been associated with acute arterial thrombosis. [Grade D]
- Thrombotic thrombocytopenia purpura (TTP) (see Chapter 23, Haemostasis: Normal physiology, disorders of haemostasis and thrombosis and their

management). Platelet infusions are contraindicated as they have been associated with TTP exacerbation: FFP (preferably by exchange transfusion) is the treatment of choice. [Grade B]

MEASURES TO AVOID TRANSMISSION OF BACTERIAL INFECTION VIA BLOOD COMPONENTS

In spite of stringent measures to minimize bacterial contamination of donated blood, bacterial contamination still rarely occurs. Therefore, all platelets in particular, should be checked at all stages, including at the bedside, for any possible leak or damage to the bag. Any change of colour or turbidity must be regarded as suspicious of contamination and discussed with the transfusion laboratory.

BLOOD DONATION

Strict eligibility criteria are applied to prevent harm to either the patient or the donor as a result of blood donation. Blood is taken from healthy adult donors aged between 17 and 70 years. Blood donation is voluntary so that there are no incentives for donors to withhold information about their health and put patients or themselves at risk. The avoidance of the transmission of infection to the recipient of blood products is of paramount importance in transfusion medicine. Donors at high risk of infections are excluded. Donors are therefore questioned extensively before donation proceeds.

Collection of 450 mL of blood is by strict aseptic technique. Blood in the UK is currently tested for a number of markers of infection (Table 21.7), but there is a ‘window period’ for each, when the donor may have recently acquired an infection but the marker will not yet be detected. *Cytomegalovirus* (CMV) negative components are only provided for patients at risk of developing severe manifestations of CMV, e.g. neonates, pregnant women, bone marrow transplant patients. Testing for malaria and *Trypanosoma cruzi* is also undertaken where appropriate.

There is no evidence at present to suggest that Creutzfeldt–Jakob disease (CJD) or variant CJD (vCJD) is transmissible to humans via blood products. However,

one study shows transfusion transmitted prion disease in sheep. Additionally, prion proteins have been located on the membranes of lymphocytes and platelets and in lymphoreticular tissue. For this reason and as our knowledge of prion disease is limited, the following precautions have been adopted in the UK: Firstly fractionated plasma products, e.g. albumin and IVIg, made from pooled plasma from thousands of donors, are now made using plasma from US donors, not UK donors. Secondly, all blood components are leukodepleted, as white cells were thought to play a key role in the pathogenesis of vCJD.

BLOOD GROUPING

Blood donations are tested for ABO and Rh D groups. Most UK donations are also labelled with their c, C, e, E and Kell antigen groups so that for 80 percent of antibodies that patients have, hospitals can provide antigen-negative blood from blood kept on site.

ADVERSE REACTIONS

The complications of transfusion can be for convenience divided into immediate and delayed and those caused by immune mechanisms and nonimmune complications (Table 21.8).

Immediate transfusion reactions

ABO INCOMPATIBILITY

This is the most dangerous of transfusion reactions and can prove fatal. The reaction often starts within the first hour of the transfusion and monitoring the patient’s observations is important in detecting a reaction early.

ABO mismatch is totally preventable and most are due to human error in checking the patient’s identity at the bedside before transfusion begins.¹⁰ In addition, errors in labelling of crossmatch or G&S samples can be prevented by labelling the sample at the bedside, from the patient’s wristband only. Mortality in cases of intravascular lysis

Table 21.7 Tests for infection in blood products in the UK.

Infection	Test	Window period	Residual risk per unit transfusion
HIV	Anti-HIV 1 and 2	22 days	1 in 4 million
Hepatitis B	HBsAg	3 weeks	1 in 100,000 to 400,000
Hepatitis C	Anti-HCV, HCV NAT	13 days	1 in 3 million
Syphilis	TPHA		Less well defined
HTLV	Anti-HTLV I and II		Less well defined
CMV	Anti-CMV		

Table 21.8 Complications of transfusion.

	Immune	Nonimmune
Immediate	ABO incompatibility Febrile, nonhaemolytic reaction Urticarial rash Anaphylactic reaction Transfusion-related acute lung injury (TRALI)	Bacterial sepsis ± endotoxic shock Cardiac failure (overload) In large volume transfusions: hypothermia, hyperkalaemia, hypocalcaemia Air embolism (rare)
Delayed	Delayed haemolytic transfusion reaction (DHTR) (red cell antibodies) Post-transfusion purpura (PTP) Transfusion-associated graft-versus-host disease (TAGVHD) Immunomodulatory effects	Viral: hepatitis B, C, HIV, HTLV, CMV, parvovirus Other infections: malaria, trypanosomiasis, etc. Iron overload (long term)

secondary to ABO incompatibility is significant and of the order of 10 percent. From the annual Serious Hazards of Transfusion (SHOT) reporting scheme in the UK, two to four patients die each year and a further five to ten have serious morbidity (e.g. require renal dialysis or admission to the intensive therapy unit (ITU)) as a result of 'wrong blood' errors. A further 25–30 have the wrong blood given, but with no adverse effect, e.g. because they receive group O in error.

Clinically, the patient experiences headache, lumbar back pain, chest tightness, nausea or facial flushing. Examination of the patient may reveal tachycardia and hypotension. Fever and rigors typically follow. Microscopic or in severe cases macroscopic haematuria may be seen. Treatment consists of stopping the transfusion, giving i.v. fluids, resuscitation and management of renal failure. The blood unit and further samples for G&S, DAT, full blood count, coagulation screen, biochemistry and a urine for haemoglobinuria should be sent to the laboratory and discussed with a haematologist. [Grade D]

BACTERIAL INFECTION

Very similar symptoms of fever, tachycardia and hypotension also occur with infected blood components being transfused. Antibiotics need to be given before a definitive diagnosis is made. This should be done in accordance with the hospital's current antibiotic protocol. Management of the patient is again by resuscitation and plain fluids and treatment of any renal failure. [Grade D]

FEBRILE, NONHAEMOLYTIC TRANSFUSION REACTIONS

Patients may develop a fever and sometimes rigors during transfusions. This is thought to be due to release of cytokines during storage, but has not been prevented totally by leukodepletion. These reactions are harmless but clinicians must make sure that severe reactions, e.g. bacterial sepsis or wrong blood reactions are not mistaken for these.

ALLERGIC REACTIONS

These may occur when a blood component contains a plasma protein to which the patient is allergic and has IgE antibodies and occur in about 1 percent of transfusions. They often result in mild urticarial reactions and are usually treated with an antihistamine with or without hydrocortisone. However, severe reactions may rarely occur leading to anaphylaxis. These may be seen in patients who are deficient in IgA, who may make anti-IgA antibodies, which can react with IgA normally present in blood components, causing anaphylaxis. In known IgA-deficient patients undergoing surgery, it is important that the haematology department is told well in advance of any elective procedure as it requires planning in order to have an IgA-deficient donor or washed products on standby.

TRANSFUSION-RELATED ACUTE LUNG INJURY

This is a rare but often severe complication. During, or soon after transfusion, particularly of FFP or platelets, patients became markedly hypoxic, dyspnoeic and may require ventilation and it is sometimes fatal. Transfusion-related acute lung injury (TRALI) is caused by anti-leukocyte (or neutrophil) antibodies in the donor's plasma, which match the specificity of the patient's white blood cells (WBC), causing aggregation of WBC in the patient's lung vasculature, causing tissue destruction.

FLUID OVERLOAD

This can be avoided by giving a diuretic with alternate units of blood if necessary.

LARGE VOLUME TRANSFUSION

Hypothermia may occur and can be minimized by infusing blood via a blood warmer. Hyperkalaemia, due to a large volume of stored blood, in which red cells have leaked some potassium, does not usually require

management). Platelet infusions are contraindicated as they have been associated with TTP exacerbation: FFP (preferably by exchange transfusion) is the treatment of choice. [Grade B]

MEASURES TO AVOID TRANSMISSION OF BACTERIAL INFECTION VIA BLOOD COMPONENTS

In spite of stringent measures to minimize bacterial contamination of donated blood, bacterial contamination still rarely occurs. Therefore, all platelets in particular, should be checked at all stages, including at the bedside, for any possible leak or damage to the bag. TRANSFUSION-RELATED ACUTE LUNG INJURY

This is a rare but often severe complication. During, or soon after transfusion, particularly of FFP or platelets, patients became markedly hypoxic, dyspnoeic and may require ventilation and it is sometimes fatal. Transfusion-related acute lung injury (TRALI) is caused by anti-leukocyte (or neutrophil) antibodies in the donor's plasma, which match the specificity of the patient's white blood cells (WBC), causing aggregation of WBC in the patient's lung vasculature, causing tissue destruction.

FLUID OVERLOAD

This can be avoided by giving a diuretic with alternate units of blood if necessary.

LARGE VOLUME TRANSFUSION

Hypothermia may occur and can be minimized by infusing blood via a blood warmer. Hyperkalaemia, due to a large volume of stored blood, in which red cells have leaked some potassium, does not usually require

- ✓ If a patient has a marked reaction during a blood transfusion, stop the transfusion and discuss urgently with the transfusion laboratory and a haematology doctor. 'Wrong blood' (ABO incompatible) or bacterial infection of blood should be considered and treated promptly. Other possibilities include TRALI and anaphylaxis due to IgA deficiency.

Deficiencies in current knowledge and areas for future research

For a decade, considerable sums of money have been spent on reducing infectious risks of transfusion in the UK, yet it is often used unnecessarily. There is a lack of, and a need for, good clinical trials to understand when transfusion will be effective. These could then facilitate a balanced approach to risk reduction which could be understood and accepted by a well-informed public.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words erythropoiesis, blood dyscrasias, leukaemia, lymphoma and plasma cell.

PERIOPERATIVE MANAGEMENT OF SICKLE CELL DISEASE

The data in this section are supported by a Medline search using the key words sickle cell disease, operative management, tonsillectomy, adenoidectomy and myringotomy.

INTRODUCTION

Patients with underlying haematological disease may present initially to the otorhinolaryngology surgeon, for example with epistaxis or lymphadenopathy. Many diseases affecting the ear, nose and throat or their treatments may have significant haematological effects. This chapter seeks to provide an understanding of the oncological aspects of the haematological system and haemato-oncology as a means of assisting prompt diagnosis.

NORMAL HAEMOPOIESIS

Physiology of blood

Blood consists of:

- red cells;

- white cells:
 - granulocytes: neutrophils, eosinophils, basophils;
 - mononuclear cells: lymphocytes, monocytes/macrophages.
- platelets;
- plasma, which contains soluble fibrinogen (serum is what remains after fibrin clot has formed).

Haemopoiesis (blood cell formation)

SITE OF HAEMOPOIESIS

Foetal haemopoiesis occurs in the yolk sac for the first few weeks of gestation and then in the liver and spleen. From about six months' gestation, haemopoietic stem cells migrate to the bone marrow and this becomes the principal site of haemopoiesis. In infancy, the majority of bone marrow is haemopoietic but during childhood there

is progressive replacement by fatty tissue. By adulthood only the proximal ends of long bones and the central skeleton are haemopoietic.

Extramedullary haemopoiesis, i.e. resumption of blood cell formation in the liver or spleen, occurs in pathological states such as thalassaemias and myelofibrosis as a means of increasing production of haemopoietic cells.

HAEMOPOIETIC STEM CELLS

All blood cells are derived from pluripotential stem cells within the bone marrow, which differentiate into progenitor cells that are committed to a specific lineage, e.g. the erythroid progenitor (burst-forming unit erythroid (BFU-E)), the granulocyte/macrophage progenitor (colony-forming unit, granulocyte-macrophage (CFU-GM)) and the megakaryocyte progenitor (colony-forming unit, megakaryocyte (CFU-Mk)) (Figure 22.1). Pluripotential stem cells also have the capability of self-renewal which ensures a constant cellularity and ability to respond with increased production of a particular cell line when needed. Stromal cells within the bone marrow microenvironment produce growth factors which coordinate the production of lineage-specific progenitors. These include glycoproteins such as stem cell factor, interleukin-3 and granulocyte colony-stimulating factor (G-CSF). Erythropoietin (EPO) is produced by renal interstitial cells in response to low oxygen tissue tensions. It acts on committed erythroid precursors to induce proliferation and inhibit apoptosis. Recombinant G-CSF and EPO are available for therapeutic use.

RED CELLS

Erythropoiesis

For effective erythropoiesis, the marrow requires:

- metals – iron, cobalt;
- vitamins – B₁₂, folate, C, E, thiamine, B₆ and riboflavin;
- hormones – thyroxine and androgens.

As red cell precursors mature in the bone marrow, the haemoglobin (Hb) content in the cytoplasm increases, the nuclear material condenses and the nucleus is eventually lost before the red cell is released from the marrow as a reticulocyte, which still contains RNA for globin chain synthesis. These cells circulate for one to two days and lose their RNA whilst passing through the spleen, leaving a mature erythrocyte, which is a non-nucleated biconcave disc. If nucleated red blood cells (RBC) are seen in a blood film, this is abnormal and indicates extramedullary haemopoiesis, bone marrow infiltration or severe sepsis. Red cells normally survive for 120 days before destruction in the reticuloendothelial system. Reticulocytes normally comprise 1–2 percent of the red cell population.

Haemoglobin

Adult haemoglobin (HbA) is a tetramer of two α and two β globin chains ($\alpha_2\beta_2$). The minor haemoglobin, HbA₂ ($\alpha_2\delta_2$), is present in adults and is less than 3 percent of

Figure 22.1 Schematic representation of haemopoiesis.

total haemoglobin. Foetal haemoglobin ($\alpha_2\gamma_2$) is normally replaced by HbA during the first six months of life.

Haem synthesis occurs in the mitochondria and requires vitamin B6. Each haem molecule combines with a globin chain and when a tetramer is formed, the four haem groups reside in 'haem pockets' in which the amino acids in the globin chains are positioned to keep the iron in a ferrous state such that it can associate reversibly with oxygen. The main function of erythrocytes is to carry Hb in adequate concentration to enable oxygen delivery to the tissues. When oxygen combines with the haem group, conformational change occurs so that the molecule has a greater affinity for oxygen. Other molecules, such as hydrogen ions and 2,3-diphosphoglycerate (2,3DPG), maintain the haem in its low affinity form and thus permit unloading of oxygen at the low pH of tissues. This property of the haem molecule explains the sigmoid form of the oxygen dissociation curve. For example, in anaemia 2,3DPG levels are increased and thus unload oxygen more readily.

Haematological blood investigations

THE FULL BLOOD COUNT

Automated cell counters are used to measure Hb and the number and size of red cells, white cells and platelets. Other indices such as the mean corpuscular volume (MCV) are derived from these results (Table 22.1). Blood for a full blood count (FBC) is taken in a tube anticoagulated with ethylenediaminetetraacetic acid (EDTA) and analysed as soon as possible to prevent storage artefacts. Increasingly, near-patient testing facilities such as the 'HemoCue' are available in the operating theatre or recovery room to provide more rapid results,

albeit for the Hb concentration. In anaemia or acute blood loss, the absolute reticulocyte count should rise because of erythropoietin increase.

Erythrocyte sedimentation rate

Erythrocyte sedimentation rate (ESR) is the rate of fall of red cells in a column of blood and is a measure of the acute phase response. A raised ESR reflects an increase in the number of large plasma proteins such as immunoglobulins and fibrinogen, which cause the red cells to clump together and fall more rapidly. Causes of a markedly raised ESR (e.g. >100 mm/hour) include malignancy, tuberculosis, temporal arteritis and myeloma. Causes of a mildly raised ESR include anaemia, female sex and increasing age. The ESR may be a useful pointer if one of the above diseases is suspected, but is not specific and further definitive tests would be needed.

Plasma viscosity

Viscosity provides similar information to the ESR but is not affected by sex or Hb.

Anaemias

Anaemia is a reduction in the Hb concentration of blood below normal values. This may be caused by an increased plasma volume, for example haemodilution, as well as a reduced circulating red cell mass.

CLINICAL ASSESSMENT

Anaemia is not a specific condition and the underlying cause must be sought. If anaemia is detected preoperatively the clinical history and simple investigations will

Table 22.1 Normal adult ranges.

	Males	Females	Males and females
Haemoglobin	13.5–17.5 g/dL	11.5–15.5 g/dL	
Red cells	$4.5\text{--}6.5 \times 10^{12}/\text{L}$	$3.9\text{--}5.6 \times 10^{12}/\text{L}$	
Haematocrit	0.40–0.52	0.36–0.48	
MCV			80–95 fL
MCH			27–34 pg
MCHC			20–35 g/dL
White cells			
Total			$4.0\text{--}11 \times 10^9/\text{L}$
Neutrophils			$2.5\text{--}7.5 \times 10^9/\text{L}$
Lymphocytes			$1.5\text{--}3.5 \times 10^9/\text{L}$
Monocytes			$0.2\text{--}0.8 \times 10^9/\text{L}$
Eosinophils			$0.04\text{--}0.44 \times 10^9/\text{L}$
Basophils			$0.01\text{--}0.1 \times 10^9/\text{L}$
Platelets			$150\text{--}400 \times 10^9/\text{L}$
Reticulocytes			$20\text{--}130 \times 10^9/\text{L}$

MCH, mean corpuscular haemoglobin; MCHC, mean corpuscular haemoglobin concentration.

usually reveal the diagnosis, allow correction of anaemia and prevent unnecessary blood transfusions.

The history should focus on:

- duration of symptoms such as shortness of breath, fatigue, lethargy;
- bleeding especially from the gastrointestinal (GI) tract;
- family history;
- past history including gastrectomy;
- dietary history;
- drug history, including non-prescribed medication.

The examination may be unhelpful, but general signs of anaemia such as tachycardia, flow murmurs and congestive cardiac failure and more specific signs such as koilonychia ('spooning' of the nails seen in iron deficiency anaemia), jaundice and stomatitis should be sought.

Investigations

The most useful guide to further investigating anaemia is the MCV. This divides anaemia into microcytic, normocytic and macrocytic (Table 22.2).

Clues can also be gained from the WBC and platelet count: pancytopenia is suggestive of a more generalized marrow defect and during bleeding the anaemia is often accompanied by a reactive thrombocytosis.

MICROCYTIC ANAEMIAS

Iron deficiency is the most common cause of a microcytic, hypochromic anaemia worldwide. The major differential diagnoses are anaemia of chronic disease and thalassaemia, which is discussed below under Thalassaemias. The investigation of a microcytic anaemia (MCV <80) should therefore include serum iron, transferrin saturation, serum transferrin receptor, total iron binding capacity (TIBC), ferritin and haemoglobin electrophoresis (if indicated by the patient's ethnic origin) (Table 22.3).

Iron-deficiency anaemia

In men the daily iron requirement is 1 mg/day and in menstruating women it is 2–3 mg/day. Circulating Hb accounts for about 75 percent of total body iron (3–4 g) and the remainder is stored as ferritin and haemosiderin. There is no physiological route for iron excretion and homeostasis is achieved by regulation of the absorption of ferrous iron across the duodenal enterocytes. Hepcidin has been putatively proposed as the mediator of iron homeostasis.

The blood film characteristically shows hypochromic microcytic red cells and pencil cells. The underlying cause should be presumed to be blood loss until proven otherwise. Patients should be asked about diet, menstrual losses, GI symptoms and bleeding. Oral iron supplementation (i.e. ferrous sulphate 200 mg three times a day) can be started whilst the cause is being elucidated and a rise in Hb of 1 g per week and a reticulocytosis within a few days of starting iron should be expected.

Anaemia of chronic disease

This is common in chronic infection, inflammation, connective tissue diseases and malignancy. The mechanisms

Table 22.3 Identification of causes of anaemia from iron studies.

	IDA	AoCD	Thalassaemia
MCV/MCH	↓	↓↑	↓↓
Serum iron	↓	↓	↔
TIBC	↑	↓	↔

AoCD, anaemia of chronic disease; IDA, iron deficiency anaemia; TIBC, total iron binding capacity.

Table 22.2 Identification of causes of anaemia by mean corpuscular volume result.

Microcytic	Normocytic	Macrocytic
MCV <80 fL	MCV 80–100 fL	MCV >80 fL
Iron deficiency	With reticulocytosis: haemolysis or acute blood loss	If MCV >100 Megaloblastic: vitamin B ₁₂ or folate deficiency
Thalassaemia	With normal or low reticulocyte count: Anaemia of chronic disease (some cases), renal disease, bone marrow failure, mixed deficiencies	Nonmegaloblastic: alcohol, liver disease, myelodysplasia
Anaemia of chronic disease (some cases)		
Lead poisoning		
Sideroblastic anaemia (some cases)		

responsible include an increase in iron retention in the reticuloendothelial system, cytokine-mediated inhibition of erythroid progenitor proliferation and a blunted erythropoietin response.

The blood film shows hypochromic microcytic red cells as seen in iron deficiency anaemia (IDA). If the markers in **Table 22.3** cannot differentiate between IDA and anaemia of chronic disease (AoCD), a bone marrow aspirate may be required to determine if iron stores are absent, indicating iron deficiency.

Thalassaemias

This group of disorders is discussed below under Thalassaemias.

Congenital sideroblastic anaemia

This group of disorders is characterized by a defect in protoporphyrin incorporation into the haem molecule. It is diagnosed by finding sideroblasts in the bone marrow which are abnormal erythroblasts with rings of iron granules.

Lead poisoning

A blood film shows hypochromic microcytic red cells and many red cells with basophilic stippling (of which there are many causes). Lead levels would be required.

MACROCYTIC ANAEMIAS

The causes of a macrocytic anaemia ($MCV > 100$) are broadly divided into megaloblastic and nonmegaloblastic causes (see **Table 22.2**). Megaloblasts are premature erythrocytes with delayed nuclear maturation relative to that of the cytoplasm due to defective DNA synthesis. Initial investigations should include B_{12} and red cell folate levels.

Megaloblastic

In B_{12} or folate deficiency, there are oval macrocytes and hypersegmented neutrophils. Once B_{12} and red cell folate levels have been requested, then both B_{12} and folate replacement may be started until results are available. A rise in reticulocyte count and a rise in Hb of 1 g per week would be expected.

Vitamin B_{12} deficiency

Vitamin B_{12} is synthesized solely by microorganisms and is present only in food of animal origin. Absorption is dependent on intrinsic factor (IF), which is secreted by gastric parietal cells. The B_{12} complex is absorbed at the terminal ileum and is transported into the blood by transcobalamin II. Body stores, of which over half is in the liver, equate to approximately 3 mg, which is sufficient for three years.

Cause of vitamin B_{12} deficiency include inadequate intake, IF deficiency (e.g. pernicious anaemia (PA)),

post-gastrectomy or small intestinal disease. Particular attention should be paid to dietary history, family history of autoimmune disease and signs and symptoms of small bowel disease. Patients should be examined for evidence of a peripheral neuropathy. Intrinsic factor and parietal cell antibodies should be checked if PA is suspected. This is an autoimmune disease in which the gastric mucosa becomes atrophied. Intestinal metaplasia may occur and there is an increased risk of gastric carcinoma (2–3 percent of all cases of PA). Endoscopy should therefore be performed if there are symptoms of dyspepsia.

It is important to ascertain whether B_{12} -deficient patients have the capacity to absorb the vitamin normally. In the UK this is done by the Schilling test, which measures urinary excretion of B_{12} . The patient is given an oral dose of radioactively labelled B_{12} and a large dose of nonlabelled B_{12} . This serves to 'flush' the labelled B_{12} into the urine. In patients with dietary deficiency, absorption and excretion will be normal. In patients with PA, previous gastrectomy or intestinal malabsorption, the excretion is reduced. Such patients are then given a second dose of labelled B_{12} with IF. Patients with PA or gastrectomy will then show normal excretion whereas those with intestinal malabsorption will still fail to absorb B_{12} . If B_{12} and iron deficiency are found, coeliac disease needs to be considered and an endoscopy is required.

Folic acid deficiency

Folic acid is present in most foodstuffs, the highest concentrations in liver and green vegetables. Body stores are sufficient for only four months.

Causes of folic acid deficiency include poor diet, malabsorption (for example, with coeliac disease), excess utilization (for example, pregnancy, haemolysis, malignancy, inflammatory disease), drugs (for example, anti-convulsants), alcoholism and liver disease.

Nonmegaloblastic ($MCV < 100$)

In myelodysplastic syndrome (MDS), the blood film may reveal dysplastic red cells, neutrophils and abnormal platelets. There may be a pancytopenia. A bone marrow including cytogenetic analysis is needed to confirm the diagnosis. The blood film in liver disease may show target cells and thrombocytopenia.

NORMOCYTIC ANAEMIA

A normochromic, normocytic anaemia is seen in a wide variety of disorders. Depending on findings of the clinical history, initial investigations may include a reticulocyte count, blood film, renal function, liver and thyroid function tests, acute phase reactants and clotting screen. If these are not diagnostic, a bone marrow aspirate may be required.

Causes of this type of anaemia are outlined in **Table 22.2**.

Preoperative management of normochromic/normocytic anaemias

If the underlying cause of anaemia cannot be treated before surgery, blood transfusion should only be given when necessary, because of the residual risks of bacterial infection or receiving the incorrect transfusion (see Chapter 21, Blood groups, blood components and alternatives to transfusion). There has been one prospective series of ten patients awaiting major head and neck oncology surgery who received erythropoietin preoperatively. Eight patients experienced a significant increase in Hb.¹ There are no randomized controlled trials using erythropoietin perioperatively, but it may be useful in patients with cultural or religious objections to allogeneic transfusion.² [Grade D]

HAEMOLYTIC ANAEMIA

The rate of red cell destruction is increased, but as the normal adult marrow is capable of producing red cells at six times the normal rate, anaemia may not be seen clinically until red cell survival is less than 30 days.

Patients should be questioned regarding family history, racial origin, drug and toxin exposure, recent blood transfusions and infective symptoms. Clinically the patient may show fluctuating jaundice, splenomegaly, acrocyanosis (including of the ears) and urine that darkens on standing due to the presence of excess urobilinogen. Intravascular haemolysis can cause haemoglobinuria.

Causes of a haemolytic anaemia include:

- intrinsic RBC abnormality:
 - membrane defects, e.g. hereditary spherocytosis;
 - metabolic defects, e.g. glucose-6-phosphate deficiency (G6PD);
 - Hb defect, e.g. sickle cell, thalassaemia.
- extrinsic RBC abnormality:
 - antibody-mediated, e.g. haemolytic transfusion reactions, autoimmune;
 - RBC fragmentation.
 - prosthetic heart valves;
 - microangiopathic haemolytic anaemia;
 - disseminated intravascular coagulation.
 - infections:
 - EBV;
 - Mycoplasma;
 - *Plasmodium falciparum* malaria;
 - chemicals and drug damage;
 - paroxysmal nocturnal haemoglobinuria.

Table 22.4 shows the investigations that confirm a haemolytic anaemia and further investigations should be directed by the history. In a postoperative setting, drugs and transfusion history should be elucidated. Depending on the blood film, haemoglobin electrophoresis (if not done preoperatively), G6PD and a direct antiglobulin test should be considered. The management of these conditions is tailored to the underlying condition, but all

Table 22.4 Laboratory investigations for haemolytic anaemia.

Presence of haemolysis	Compensatory increase in erythropoiesis
Increased unconjugated bilirubin	Reticulocytosis (a bone marrow test, if required, would show erythroid hyperplasia)
Increased LDH	
Absent haptoglobin (circulating protein which binds Hb)	
Increased urinary urobilinogen	

LDH, lactate dehydrogenase.

benefit from folic acid 5 mg daily. Iron deficiency does not occur unless there is intravascular haemolysis and iron is lost through the urine. Autoimmune cases are often managed with immunosuppression and if longstanding, this should not be stopped perioperatively. Patients with known haemolytic anaemias should be discussed with a haematologist preoperatively.

HAEMOGLOBINOPATHIES

The haemoglobinopathies are inherited disorders of haemoglobin structure or its production.

SICKLING DISORDERS

This group of disorders includes the homozygous state (HbSS), and co-inheritance of the sickle cell gene with β thalassaemia or with other Hb variants, e.g. HbSC disease. HbSS is found most commonly in Afro-Caribbeans but also seen in Mediterranean populations, the Middle East and India. HbS differs from HbA by the substitution of valine for glutamic acid at position 6 of the β chain. During deoxygenation, the abnormal Hb molecules form linear stacks causing the RBC to deform into a rigid sickle shape. These cells have difficulty passing through the microcirculation resulting in obstruction of small vessels and tissue infarction. Sickle cells also have a shortened survival.

The clinical course is highly variable but usually presents from three months onwards with anaemia and mild jaundice. In older patients vaso-occlusive problems occur as a result of sickling in the small vessels of any organ. Patients may present with:

- painful crises;
- aplastic crises;
- sequestration crises when sickled RBC pool in the liver or spleen;
- chest syndrome which is characterized by tachycardia, fever, profound hypoxaemia, falling Hb and bilateral chest signs;
- cerebrovascular accident.

Investigations reveal a steady state Hb between 5 and 11 g/dL, mildly raised WBC and platelets. There is a reticulocytosis and mildly elevated lactate dehydrogenase (LDH) and bilirubin. A sickle solubility test detects the presence of HbS, but cannot distinguish sickle trait from HbSS or HbSC. Hb electrophoresis is required to confirm the diagnosis. All patients from at-risk populations should have Hb electrophoresis (or at least a sickle solubility test) done prior to a general anaesthetic.³ [Grade D] In patients with recurrent crises, hydroxyurea has been shown to improve the clinical course which is, in part, explained by its ability to increase HbF levels.⁴ [Grade C]

Perioperative management of sickle cell disease

Surgery of the ear, nose and throat accounts for about 20 percent of all surgical procedures in this group. Surgical procedures may be complicated by hypoxia, acidosis or hypothermia leading to an increased risk of sickle cell-related complications. The observed complication rate of 32 percent for tonsillectomy and/or adenoidectomy (T/A) was twice the frequency that has been reported among patients without sickle cell disease.⁵ The Cooperative Study of Sickle Cell Disease retrospectively analysed 1079 operations in patients with sickling disorders.⁶ The sickle-related complication rate (painful crisis, acute chest syndrome, cerebrovascular accident) varied with the type of procedure; in patients undergoing T/A there were no sickle cell disease-related complications in HbSS patients. In patients undergoing myringotomy, there was one sickle-related complication. In both types of operation there was no significant difference between the overall postoperative complication rate and transfusion status. Blood transfusion regimes can be used preoperatively to dilute the percentage of sickle cells, thus potentially reducing the risk of vaso-occlusive crises. The multi-institutional Preoperative Transfusion Study⁶ directly compared an aggressive transfusion approach in which the percentage of HbS was reduced to less than 30 percent (achieved by exchange transfusion), to a conservative approach in which the target Hb was 10 g/dL (achieved by top-up transfusion). This included 165 patients who underwent T/A or myringotomy. There was no difference in complication rates between the two groups. A previous history of pulmonary disease identified patients as at risk for sickle cell-related events undergoing T/A. This was the only trial that met the criteria for the Cochrane Database Review assessing preoperative blood transfusions for sickle cell disease (SCD).⁷ There are no available data comparing exchange transfusion with no transfusion at all. [****/***]

In the absence of a study comparing transfusion versus no transfusion it seems reasonable to consider top-up transfusion in HbSS to a Hb of 10 g/dL, unless there is a history of pulmonary complications or other markers of severe disease. [Grade C] In such cases it would seem more appropriate to exchange transfuse preoperatively

aiming for ≤ 30 percent Hbs. [Grade D] Other cases are considered on an individual basis. Factors such as length of operation and presence of alloantibodies should be taken into account. [Grade D] Adenotonsillar hypertrophy is linked with obstructive sleep apnoea which in turn is a risk factor for cerebrovascular disease in SCD.⁸ Careful preoperative assessment is therefore needed as a more aggressive transfusion approach may be indicated in such patients. [Grade D]

All patients with sickling disorders should be:

- discussed with an anaesthetist and haematologist;
- kept warm, well hydrated and oxygenated; [Grade C]
- monitored closely from a respiratory viewpoint postoperatively and measures such as spirometry and physiotherapy instituted to reduce the risk of chest syndrome;⁹ [Grade C]
- given thromboprophylaxis. [Grade D]

Postoperative blood transfusion should be discussed with a haematologist. Most patients with sickle cell trait do not require transfusion and simple precautions, such as avoiding dehydration and hypoxia, should be followed.

THALASSAEMIAS

These disorders are caused by an inherited defect in the rate of globin chain synthesis, causing underproduction of haemoglobin and imbalanced globin chain synthesis. The chains that are in excess precipitate and cause premature red cell destruction. β thalassaemias, i.e. deficiency of β chains, predominantly occur in people from the Mediterranean region, whereas α thalassaemias, i.e. a reduction of α chains, occur predominantly in people of Middle and Far Eastern origin.

α and β thalassaemia traits, where only one α and β gene has been deleted or altered, are not usually associated with anaemia but have a markedly reduced MCV. The ethnic origin, clinical history and blood film are helpful in distinguishing these conditions from IDA.

α Thalassaemias

If more than two copies of the α gene have been deleted then HbH disease results with a marked hypochromic microcytic anaemia. Complete deletion of all four α genes is not compatible with life (HbBarts).

β Thalassaemias

Patients who have mutations causing failure to produce any β chains have a serious course. Such patients usually present from three months of age with failure to thrive, anaemia and marked hepatosplenomegaly. The blood picture is grossly abnormal with marked anaemia, hypochromia, nucleated red cells, target cells and stippled cells. Most patients require lifelong regular blood transfusion. By maintaining a near normal Hb, the erythropoietic drive is suppressed and the skeleton-deforming

extramedullary haemopoiesis is curtailed. The downside for this is that patients require iron chelation to prevent organ damage from iron overload, using subcutaneous desferrioxamine infusions with or without oral deferri-prone. Most patients with thalassaemia require no major preparation perioperatively. Those patients with iron overload, however, should have their cardiac function assessed prior to a general anaesthetic.¹⁰ [Grade D] During any episode of infection, chelation therapy should be ceased until the source of the fever has been identified, as some bacteria, for example *Yersinia enterocolitica* proliferate rapidly in high blood concentrations of iron. Desferrioxamine is known to cause high frequency sensorineural hearing loss and patients should be monitored annually.

Polycythaemia

This is defined as an increase in Hb, haematocrit and red cell count. Haematocrit is a more reliable indicator of polycythaemia as Hb may be low in associated iron deficiency. Polycythaemia can be divided into:

- **Absolute** in which there is a true increase in red cell mass, or
- **Relative** in which the red cell volume is normal, but the circulating plasma volume is reduced.

Table 22.5 shows the underlying causes.

INVESTIGATIONS

Red cell isotope studies to distinguish absolute from relative polycythaemia are indicated after overt dehydration has been excluded as a cause. Secondary causes need to be considered and pulse oximetry, erythropoietin levels and carboxyHb may be required, depending on clinical findings. A bone marrow aspirate and trephine may be required to diagnose polycythaemia rubra vera (PRV).

Polycythaemia rubra vera

PRV is a clonal stem cell disorder in which there is excessive proliferation of erythroid, myeloid and

megakaryocytic progenitors. It usually presents in patients over 60 years with tiredness, visual disturbance, vertigo and tinnitus. Gout, pruritis, injected conjunctivae and splenomegaly may also be features. Increased viscosity caused by raised haematocrit and thrombocytosis (often with abnormal function) contribute to the vascular occlusive tendency. There is a paradoxical increased risk of haemorrhage and patients can present with epistaxis.

Without treatment, the median survival is 18 months; most die from cerebral thromboses. Survival is improved by repeated venesections to maintain haematocrit (Hct) below 0.45.¹¹ Hydroxyurea is also used and patients with previous vaso-occlusive events should be prescribed low-dose aspirin. [Grade C/D]

Surgery in these patients should be planned and the Hct should be less than 0.45. Abnormal platelet function should be expected and aspirin stopped. Platelet transfusions may sometimes be required: this should be discussed with a haematologist. Antithrombotic measures should be in place. Associated thrombocytosis cannot be quickly corrected – venesection may actually worsen this. [Grade C/D]

There is no evidence available to guide the management of patients who have secondary and relative polycythaemia. Perioperative management of such patients is therefore guided by the individual patient and operative risk and should be discussed with a haematologist.

WHITE CELLS

Granulopoiesis

White blood cells (WBC) can be broadly divided into granulocytes (neutrophils, eosinophils and basophils), monocytes and the immunocytes (lymphocytes and plasma cells). The major role of human WBC is host defence against microbial invaders. This is discussed in more detail in Chapter 11, Defence mechanisms.

Table 22.5 Causes of polycythaemia.

Primary	Absolute	
	Secondary	Relative
Polycythaemia rubra vera (PRV)	Compensatory increase in erythropoietin High altitudes Pulmonary disease Cardiovascular disease Familial polycythaemia Heavy cigarette smoking Inappropriate increase in erythropoietin Renal disease: cysts, renal cell carcinoma	Pseudopolycythaemia, ie: no underlying cause found Cigarette smoking Dehydration: diuretics, alcohol Plasma loss: burns, enteropathy

Granulocytes mature in the bone marrow until they become segmented neutrophils, eosinophils and basophils. Their lifespan is six to ten hours following their release into the peripheral circulation. The monocyte precursors spend only a short time in the marrow and mature in the peripheral tissues to macrophages.

Benign white cell disorders

The normal adult ranges are shown in **Table 22.1**.

NEUTROPHILIA

The primary role of the neutrophil is to engulf and kill any microbe it encounters in the extravascular tissues. The causes of neutrophilia are as follows:

- bacterial infections;
- inflammation/tissue necrosis: myocardial infarction (MI), trauma;
- metabolic disorders: uraemia, acidosis;
- neoplasia;
- acute haemorrhage and haemolysis;
- steroids;
- myeloproliferative disorders;
- treatment with myeloid growth factors.

The blood film may show a 'left shift' in which there is an increase in the number of neutrophil precursors. Neutrophilia and a 'left shift' together are called a 'leukaemoid reaction', which is seen in severe sepsis, with G-CSF administration and in chronic myeloid leukaemia (CML). A 'leukoerythroblastic blood film' refers to the presence of immature granulocytes and nucleated red cells and if it is not explained by severe sepsis or hypoxia indicates bone marrow infiltration by tumour or fibrosis and is an indication for a bone marrow biopsy.

Table 22.6 Causes of neutropenia.

Congenital	Acquired
Kostmanns syndrome	<p>Drug induced:</p> <p>Antibacterials (co-trimoxazole, chloramphenicol, imipenem)</p> <p>Anticonvulsants (phenytoin, carbamazepine)</p> <p>Antithyroids (carbimazole)</p> <p>Immunosuppressive agents (azathioprine, chemotherapy)</p> <p>Infections:</p> <p>Viral (HIV, hepatitis, influenza)</p> <p>Fulminant bacterial infection</p> <p>Racial</p> <p>Familial</p> <p>Cyclical</p> <p>Immune:</p> <p>Autoimmune</p> <p>Systemic lupus erythematosus</p> <p>Felty's syndrome</p> <p>Anaphylaxis</p> <p>Part of pancytopenia</p>

NEUTROPENIA

This is defined as a neutrophil count of $<2.0 \times 10^9$. In Blacks, the lower range is 1.5. The causes are outlined in **Table 22.6**. The risk of infection is more severe when the count is <1.0 and when the cause reflects bone marrow failure or chemotherapy. Isolated neutropenia can simply be observed but if any other counts are affected then a bone marrow biopsy should be performed.

Any patient with neutropenia undergoing instrumentation should have antibiotic prophylaxis.¹² [Grade D]

PANCYTOPENIA

Neutropenia may be one manifestation of pancytopenia which is defined as a reduction in the blood count of all the major cell lines – red cells, white cells and platelets. It reflects either reduced bone marrow production or increased peripheral destruction. The causes of pancytopenia are outlined in **Table 22.7**. Bone marrow examination should be performed in all patients with pancytopenia.

Table 22.7 Causes of pancytopenia.

Decreased bone marrow function	Increased peripheral destruction
Aplasia	Splenomegaly
Acute leukaemia, myelodysplasia, myeloma	
Infiltration with lymphoma, solid tumours, tuberculosis	
Megaloblastic anaemia	
Paroxysmal nocturnal haemoglobinuria	
Myelofibrosis	
Haemophagocytic syndrome	

EOSINOPHILS

Eosinophils have important antiparasitic activity and play a role in allergic responses. The causes of eosinophilia (>0.4) are outlined in Table 22.8.

LYMPHOCYTOSIS

Lymphocytes are responsible for adaptive immunity; T lymphocytes are responsible for cell-mediated immunity and B lymphocytes for humoral immunity. This is further explored in Chapter 11, Defence mechanisms. The causes of a lymphocytosis are outlined in Table 22.9. In children, lymphocytosis occurs as a response to acute infections; in adults a neutrophilia is more often seen in glandular fever. Large numbers of atypical lymphocytes are seen in the peripheral blood. A monospot test is usually positive by the second week if this is the underlying diagnosis.

Table 22.8 Causes of eosinophilia.

Cause	Example
Allergic diseases	Asthma, hayfever, urticaria, Churg–Strauss syndrome
Parasitic diseases	Amoebiasis, hookworm, ascariasis, tapeworm
Recovery from acute infection	
Skin disorders	Psoriasis, pemphigus, dermatitis herpetiformis
Pulmonary eosinophilia and the hypereosinophilic syndrome	
Drug sensitivity	
Polyarteritis nodosum	
Hodgkin’s disease	
Metastatic malignancy	
Eosinophilic leukaemia	
Treatment with G-CSF	

Table 22.9 Causes of lymphocytosis.

Cause	Example
Infections	Acute: infectious mononucleosis, rubella, pertussis, mumps, hepatitis, cytomegalovirus, HIV, herpes simplex or zoster Chronic: tuberculosis, toxoplasmosis, brucellosis, syphilis
Chronic lymphocytic leukaemias	
Acute lymphoblastic leukaemia	
Non-Hodgkin’s lymphoma	
Thyrotoxicosis	

LYMPHOPENIA

Lymphopenia (peripheral blood lymphocytes <1.0) may occur in severe bone marrow failure, in autoimmune disorders, with immunosuppressive therapy, post-viral infection and in immune deficiency syndromes, such as human immunodeficiency virus (HIV).

MALIGNANT WHITE CELL DISORDERS

The haemopoietic malignancies are clonal disorders that derive from a single cell in the bone marrow or lymphoid tissue that has undergone genetic alteration. In the majority of cases neither a genetic susceptibility nor an environmental agent can be implicated. Increasingly, specific genetic abnormalities are used to tailor treatment protocols. For example, acute myeloid leukaemia associated with the t(15;17) translocation results in fusion of the PML gene to the retinoic acid receptor α gene, RAR α . The resultant PML-RAR α fusion protein acts as a transcription repressor instead of the wild type, which is an activator. Patients are therefore treated with high doses of all-trans retinoic acid (ATRA), which causes differentiation of the leukaemia cells and an improved prognosis.

ACUTE LEUKAEMIAS

This group of disorders is defined as a malignant proliferation of myeloid stem cells showing defective maturation. For the diagnosis to be confirmed, the bone marrow must contain greater than 20 percent blasts. Acute lymphoblastic leukaemia (ALL) is more common in children, whereas, acute myeloid leukaemia (AML) is more frequently seen in adults. Patients present acutely, often critically unwell with signs and symptoms related to bone marrow failure or leukostasis.

Both AML and ALL can present with:

- signs and symptoms related to anaemia;
- bleeding including DIC in AML with t(15;17);
- headaches, blurred vision, dizziness, shortness of breath secondary to leukostasis;
- infections secondary to neutropenia: oral herpetic lesions; oral candidiasis; chest, perianal and skin infections.

AML with monocytoid blasts can also present with gum and skin infiltration. Patients with ALL can have lymphadenopathy, hepatosplenomegaly and CNS involvement. Any patient presenting with atypical oral infections should have a FBC and blood film at presentation. Abnormal leukaemic cells are often present in the blood film, but a bone marrow test is required to establish the exact diagnosis. These patients must be referred to the haematology team without delay. Treatment involves high-dose combination chemotherapy and sometimes a bone marrow or stem cell transplant.

Lymphomas, which involve the reticuloendothelial system, can also have a leukaemic component to them, i.e. overspill into the peripheral circulation. Although bone marrow biopsy is important in staging lymphoma, it is not often infiltrated, so is not a first-line test in establishing the diagnosis. A lymph node biopsy is usually required to make a diagnosis.

CHRONIC LEUKAEMIAS

The chronic leukaemias are distinguished from the acute leukaemias by their slower progression. They are also more difficult to cure.

CHRONIC MYELOID LEUKAEMIA

This is a clonal disorder of a pluripotent stem cell. The clinical features such as weight loss, lassitude and splenomegaly can be explained by the great increase in total body myeloid cell mass. The diagnosis is usually relatively straightforward due to the finding of the BCR-ABL gene in 95 percent of patients. This codes for a fusion protein with excess tyrosine kinase activity. Patients have a grossly elevated WCC, usually above 50, which are predominantly neutrophils and myelocytes. The term 'white blood cell' was originally coined due to the appearance of these patients' blood. Patients may also present with bruising and epistaxis due to impaired platelet function.

Since 2001, STI 571, a tyrosine kinase inhibitor, has been used to treat such patients with 30 percent achieving a molecular remission. Other chemotherapy or a bone marrow or stem cell transplant may be required.¹³ [Grade C/D]

CHRONIC LYMPHOCYTIC LEUKAEMIA

Chronic lymphocytic leukaemia (CLL) is the most common adult leukaemia and is defined as a clonal proliferation of mature lymphocytes. Most cases occur in older patients and are found incidentally on a routine blood count with a mild lymphocytosis and characteristic smear cells on the blood film. Some patients, however, present with fatigue, recurrent infections (due to hypogammaglobulinaemia), hepatosplenomegaly, lymphadenopathy and autoimmune haemolytic anaemia. Diagnosis is by the immunophenotyping of peripheral blood. Treatment is reserved for those with symptoms, increasing lymphadenopathy or hepatosplenomegaly or doubling of lymphocytosis in <6 months.

PLASMA CELL DYSCRASIAS

These monoclonal proliferations of plasma cells are characterized by secretion of a single homogenous immunoglobulin product known as the M-component.

This group includes the following diseases:

- multiple myeloma;
- Waldenström's macroglobulinaemia;
- monoclonal gammopathy of uncertain significance (10 percent of patients with an isolated paraprotein eventually develop myeloma or Waldenström's macroglobulinaemia);
- AL amyloidosis;
- plasmacytomas (solitary or extramedullary).

These patients can present with:

- signs of bone marrow failure, especially infections;
- hyperviscosity, including haemorrhage, due to high levels of paraprotein (the M-component);
- bone pain or fractures;
- hypercalcaemia.

Over 80 percent of extramedullary plasmacytomas are localized to the oropharynx, nasopharynx, sinuses and larynx. Such patients should be investigated for the presence of multiple myeloma and treated with radiotherapy. Investigations should include plasma protein electrophoresis, urine for Bence-Jones protein, a skeletal survey plus a calcium level, renal function tests and a full blood count and blood film.

Bone marrow/stem cell transplantation

Bone marrow/stem cell transplantation (BMT/SCT) is used in the treatment of a wide range of haematological malignancies. Such patients, especially those receiving allogeneic transplants, are at risk of overwhelming infections. Sinus infections have been shown to occur in about one-fifth of patients undergoing allogeneic BMT¹⁴ and invasive rhinocerebral aspergillosis in 2 percent.¹⁵ Mucormycoses are also well recognized. Although there are no randomized trials to assess how such patients should be managed, the majority of such patients will be treated with systemic antifungal therapy and radical surgery. [Grade D]

PLATELETS

Thrombocytosis

Thrombocytosis is defined as a platelet count greater than $450 \times 10^9/L$. It is either primary, i.e. due to a myeloproliferative disorder such as essential thrombocytosis (ET) or a secondary, reactive phenomenon. The secondary causes are outlined in **Table 22.10**.

About one half of patients with ET are asymptomatic and the thrombocytosis is an incidental finding. The most common symptoms at presentation relate to vascular occlusion, particularly of small vessels.

Patients with ET should receive an antiplatelet agent, usually aspirin. It is important to remember that such

Table 22.10 Causes of thrombocytosis.

Primary	Secondary
Essential thrombocythaemia	Following surgery Chronic infection Inflammatory states Malignancy Chronic blood loss and iron deficiency Severely ill patients, e.g. on ITU

patients, as well as being prothrombotic are also, paradoxically, at risk of haemorrhage. Surgery in these patients needs to be planned well in advance to ensure the platelet count is <600 to reduce the risk of cerebrovascular disease. The majority of patients are controlled with hydroxyurea.¹⁶ [Grade C/D]

Secondary causes rarely cause a platelet count above 1000. Treatment is of the underlying condition. The use of antiplatelet agents in such circumstances is not clear.

Thrombocytopenias

See Chapter 23, Haemostasis: normal physiology, disorders of haemostasis and thrombosis and their management for the investigation and management of thrombocytopenias.

SPLENECTOMY

Patients who have had a splenectomy or who are functionally hyposplenic are at increased risk of overwhelming sepsis especially from encapsulated bacteria such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type B and *Neisseria meningitidis*. Functional hyposplenism occurs secondary to sickle cell anaemia, thalassaemia major, lymphoproliferative disease and coeliac disease.

The guidelines for the prevention and treatment of infection in patients with an absent or dysfunctional spleen produced by the British Committee for Standards in Haematology (BCSH) are summarized below:¹⁷

- All splenectomized patients and those with functional hyposplenism should receive pneumococcal immunization. Patients not previously immunized should receive haemophilus influenza type B vaccine. [Grade C/D] Patients not previously immunized should receive meningococcal group C conjugate vaccine. [Grade D] Influenza immunization should be given. [Grade D] Lifelong prophylactic antibiotics are still recommended (oral phenoxymethylpenicillin or erythromycin). [Grade C/D]
- Patients developing infection despite measures must be given systemic antibiotics and admitted urgently to hospital. [Grade C/D]

- Patients should be given written information and carry a card to alert health professionals to the risk of overwhelming infection. Patients may wish to invest in an alert bracelet or pendant. [Grade D]
- Patients should be educated about the potential risks of overseas travel, particularly with regard to malaria and unusual infections, for example those resulting from animal bites. [Grade C/D]
- Patient records should be clearly labelled to indicate the underlying risk of infection. Vaccination and revaccination status should be clearly and adequately documented. [Grade C/D]

KEY POINTS

- Many haematological disorders are complicated by ENT disorders.
- Anaemia should be investigated and treated preoperatively where possible – starting with FBC indices and a blood film.
- Abnormal FBC indices or symptoms suggestive of hyperviscosity should be referred to a haematologist for investigation.
- Patients without a functioning spleen are at greater risk of severe sepsis and need antibiotic cover for invasive procedures and urgent treatment for any overt sepsis.

Best clinical practice

- Preoperatively, discuss all patients with sickling disorders with an anaesthetist and haematologist – particularly any with adenotonsillar hypertrophy as associated obstructive sleep apnoea is a risk factor for cerebrovascular disease in sicklers.
- Neutropenic patients undergoing instrumental procedures should be discussed with a haematologist and have antibiotic prophylaxis.
- Patients without a spleen are at an increased risk of severe sepsis and need antibiotic cover for invasive procedures and urgent treatment of sepsis.

Deficiencies in current knowledge and areas for future research

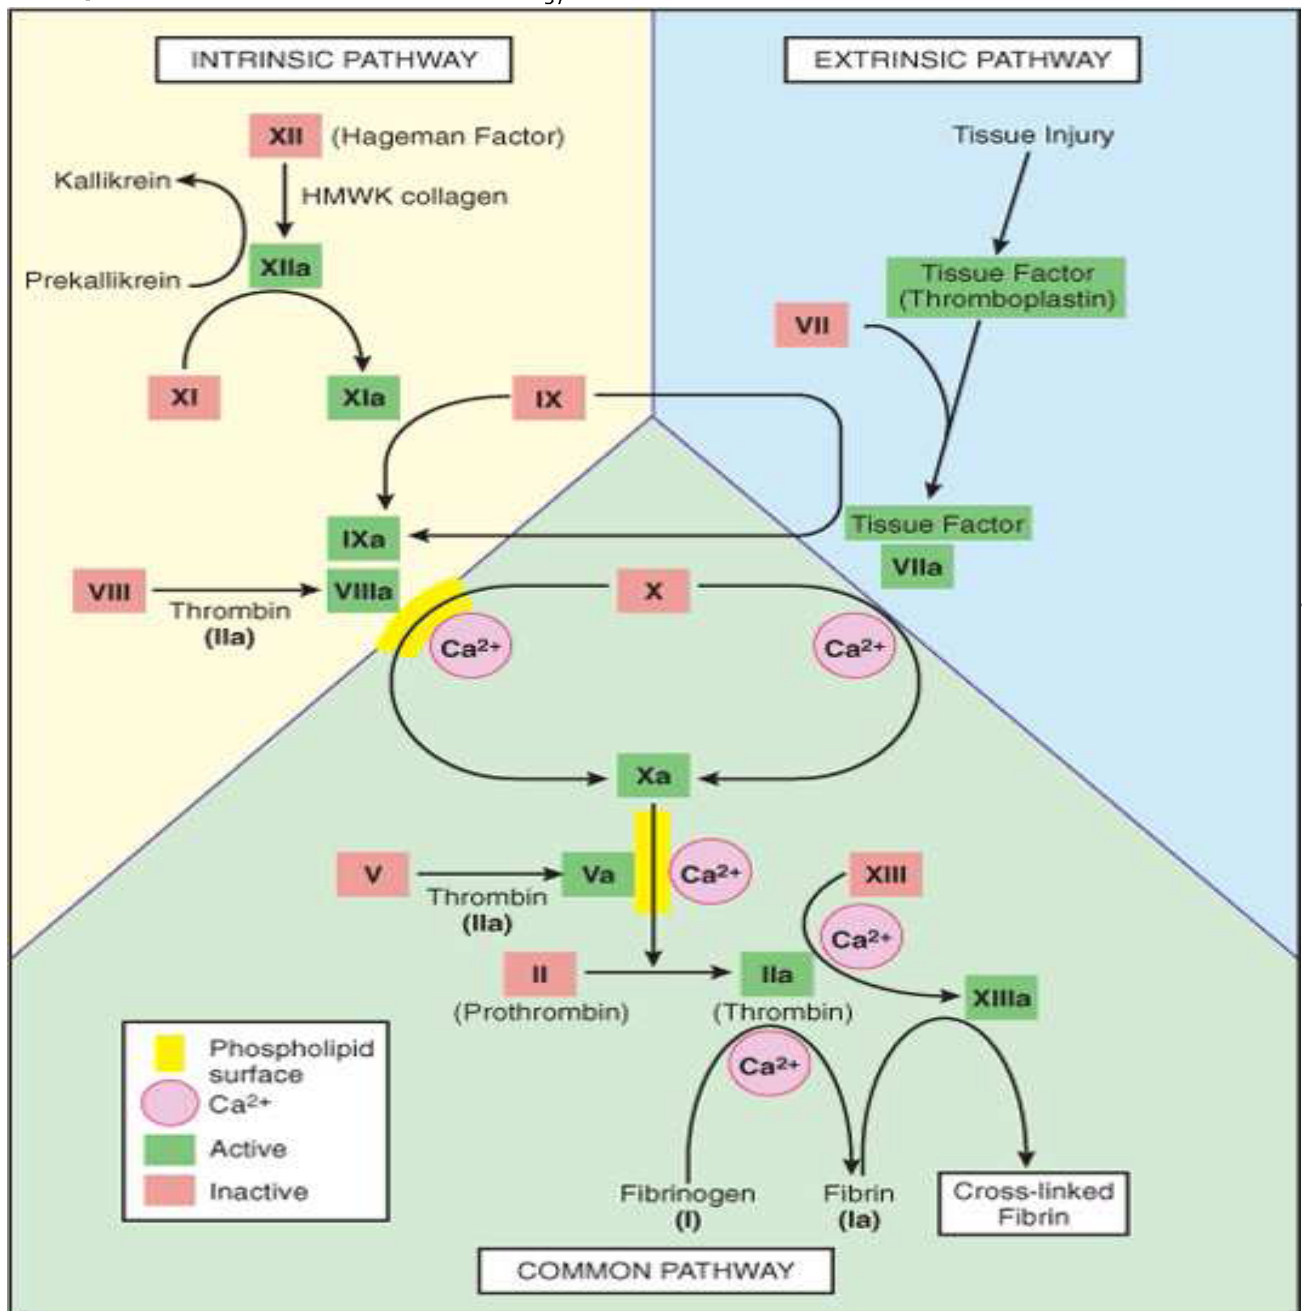

- Further trials are needed for the optimal management of essential thrombocythaemia, polycythaemia rubra vera and chronic myeloid leukaemia.

- Further trials are needed to determine the optimal transfusion management of sickle cell disease patients perioperatively.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words haemostasis, thrombosis, coagulation.

NORMAL HAEMOSTASIS

Bleeding or thrombotic problems in surgical patients are not uncommon and may occur for a variety of reasons. In order to understand the basis for these, it is important to understand the mechanisms for normal haemostasis. The haemostatic system comprises five major components: blood vessels, platelets, coagulation factors, coagulation inhibitors and fibrinolysis. These interact, using complex activating or inhibitory feedback mechanisms in order to ensure a powerful, quick, localized procoagulant response to minimize blood loss from sites of vascular injury, but without inappropriate and potentially harmful extension of the clot beyond the area of injury.¹

Blood vessels

Normally, vessel endothelial cells inhibit haemostasis as they synthesize prostaglandin I₂ (PGI₂ or prostacyclin) and nitric oxide (NO), which cause vasodilation and inhibit platelet function. However, when a vessel is injured vasoconstriction occurs and platelets come into

contact with vessel wall components which causes adhesion of platelets to the vessel wall. Von Willebrand factor (VWF), acts to further anchor platelets to vessel wall collagen.

Platelets

Platelets are fragments of cytoplasm derived from megakaryocytes in the bone marrow. About 20–30 percent of circulating platelets are normally sequestered in the spleen and the normal lifespan of platelets is 8–14 days. Following adhesion of platelets to the vessel wall, a variety of substances including ADP and thromboxane A₂ (TXA₂), induce platelet aggregation, resulting in the formation of a platelet plug at the site of vessel injury. In capillaries, platelet aggregation and vasoconstriction alone may be enough to sustain haemostasis, but in larger vessels, stabilization of the platelet plug by fibrin is required to prevent it breaking off. Coagulation factors interact with one another on the surface of activated platelets, promoting coagulation but thus localizing it to the site of injury.

Coagulation factors

FIBRIN FORMATION

In the last decade, a better understanding has been gained of the mechanisms resulting in formation of fibrin strands to stabilize the platelet plug (**Figure 23.1**).

The initiator of coagulation is the complex of tissue factor and factor VIIa (which is found in vascular endothelium and smooth muscle cells). A minute concentration of this complex can activate factor X, which has a central role in both the extrinsic and intrinsic pathways. Factor X forms a complex with calcium and factor V (the prothrombinase complex), which then cleaves prothrombin (II) to produce a minute amount of thrombin. This in turn feeds back to initiate massive activation of factors V and VIII, leading to rapid generation of vast amounts of thrombin. Thrombin in turn, as a proteolytic enzyme, cleaves fibrinogen to give polymerized insoluble fibrin strands. Factor XIII is also activated by thrombin and serves to cross-link fibrin and other proteins in the clot.

VWF is formed in endothelial cells and platelets and has two functions: it acts as a carrier for factor VIII in the circulation, stabilizing it to prevent metabolic breakdown, and it mediates platelet adhesion to collagen in the injured vessel wall.

COAGULATION INHIBITORS

Potentially, a small amount of plasma could generate enough thrombin to clot all the fibrinogen in the body in 30 seconds. Physiological anticoagulants exist to prevent this.

- **Antithrombins** (**Table 23.1**) inhibit a variety of the coagulation factors. Of note, heparin acts by both inducing a 2000-fold increase in the rate of

inactivation of thrombin by antithrombin and also by enhancing the speed of neutralization of factor Xa.

- The components of the protein C system act to neutralize active coagulation factors once they have formed. The 'protein C pathway' which includes thrombomodulins, results in formation of activated protein C, which rapidly degrades the catalytic factors VIIIa and Va. Protein S, like protein C, is a vitamin K-dependent factor synthesized in the liver. It binds to the activated protein C complex and enhances its activity ten-fold.

FIBRINOLYSIS

Fibrinolysis prevents excessive deposition of fibrin which could impede blood circulation (**Figure 23.2**). Fibrin binds plasminogen, which is converted to the active form, plasmin by plasminogen activators, e.g. tPA, uPA. Plasmin then degrades fibrin. There are in turn a number of inhibitors of fibrinolysis to curb the potential for degradation of all the fibrinogen in the body quickly. α_2 -antiplasmin inactivates free plasmin and plasminogen activator inhibitor type 1 (PAI-1) inactivates tPA.

Table 23.1 Antithrombins.

Inhibitor	Main substrates
Antithrombin ^a	IIa, Xa
Heparin cofactor II	IIa
α_1 -antitrypsin	XIa, Xa
C ₁ esterase inhibitor	Kallikrein, XIa
α_2 -anti-plasmin	Plasmin
α_2 -macroglobulin	Kallikrein
Tissues factor pathway inhibitor	Tissue factor VIIa

^aAntithrombin was formerly known as antithrombin III (ATIII).

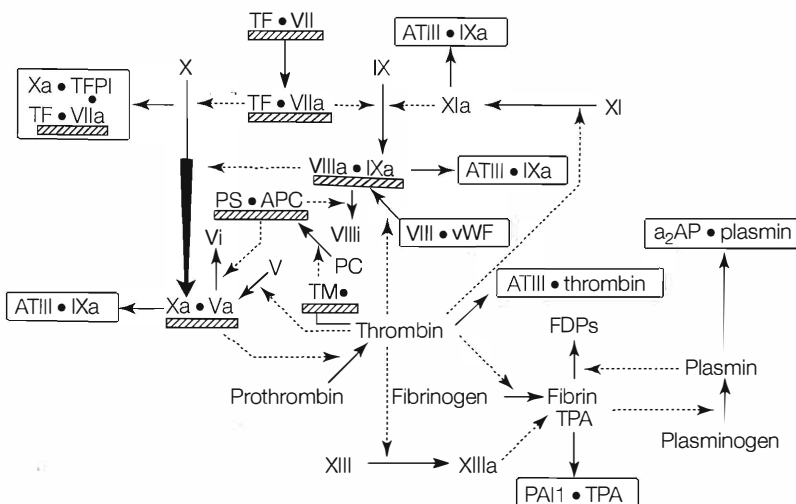

Figure 23.1 Mechanism of normal haemostasis.

Figure 23.2 The fibrinolytic system.

Laboratory tests of haemostasis

COAGULATION TESTS

These are carried out on blood samples taken into tubes containing sodium citrate, which anticoagulates blood by depleting calcium. It is crucial that the correct volume of blood is taken for the amount of citrate present in the tube, otherwise test results are rendered meaningless. Similarly, spurious results can be caused by samples taken a long time previously or by contamination with heparin, e.g. from heparin-flushed cannulae. Laboratories vary slightly in the techniques and reagents used, so each defines its own normal ranges.

PROTHROMBIN TIME

Brain extract, as a source of tissue factor, and calcium are added to the test plasma and the time to clot formation is measured. The prothrombin time (PT) is sensitive to deficiencies in factors II, V, VII, X and fibrinogen (I). The prothrombin time can be expressed as a ratio of the result obtained using normal plasma (PTR). This ratio should normally be approximately 1.0 (often it is given as the international normalized ratio (INR)).

ACTIVATED PARTIAL THROMBOPLASTIM TIME

After adding phospholipid, calcium and an activator, e.g. kaolin to the test plasma, the time to clot formation is measured. The activated partial thromboplastim time (APTT) is sensitive to deficiencies in factors XII, XI, X, IX, VIII, V, II and fibrinogen. It should be noted that it is also prolonged if there is heparin contamination, either if samples are taken from heparinized lines, or if the patient is on heparin.

THROMBIN TIME

Thrombin and calcium are added to patient plasma and the time to clot formation is measured. The thrombin time (TT) is prolonged when fibrinogen is reduced in level or dysfunctional or in the presence of thrombin inhibitors, e.g. heparin.

PLATELET COUNT

The normal range is $150\text{--}400 \times 10^9/\text{L}$. Significant bleeding would not normally be expected until the platelet count falls below $80 \times 10^9/\text{L}$.

BLEEDING DISORDERS

General assessment

Bleeding disorders may be due to abnormalities of coagulation, platelets (or rarely vascular origin) and may be inherited or acquired (Table 23.2). If a bleeding disorder is suspected, a careful clinical history and examination make important contributions in reaching a diagnosis.

TIMING

A congenital bleeding disorder may be suggested if there is a history of spontaneous bleeding (e.g. epistaxis, haemarthrosis, gastrointestinal bleeding) or bleeding after previous surgery (e.g. tonsillectomy, appendectomy, circumcision, dental extractions) or menorrhagia may be present. There may be a family history of bleeding, although not always, as for example, in haemophilia A, one-third of cases are due to new genetic mutations. Symptoms of congenital coagulation disorders usually appear early in life, but mild forms may only present after surgery or significant trauma. A history of operations including wisdom teeth extractions or childbirth without excessive bleeding makes a congenital bleeding disorder unlikely. Results of any previous platelet counts and coagulation screens are also useful.

PATTERNS OF INHERITANCE

Haemophilia A and B are X-linked disorders, so affect males, and females are carriers only (with very rare exceptions). Von Willebrand disease (VWD) and other coagulation factor and platelet disorders are not X-linked, so can affect males or females. Most forms of VWD are autosomal dominant; most other deficiencies are autosomal recessive and are much rarer than haemophilia A and B and VWD.

Table 23.2 Bleeding disorders.

	Coagulation	Platelets
Acquired	Vitamin K deficiency/liver disease	↑destruction
	Drugs (e.g. warfarin, heparin)	ITP
	DIC	TTP
	Massive transfusion	PTP
	Acquired inhibitors (rare)	Splenic pooling
		Splenomegaly
		Senile purpura
		Hereditary haemorrhagic telangiectasia
		Connective tissue disorders
		↓production
		Bone marrow failure, e.g. leukaemia
		Aplastic anaemia
		Chemotherapy
		Dysfunction
		NSAIDs
		Cardiac bypass/ECCs
		Renal failure
Inherited	Haemophilia A (VIII deficiency)	(rare)
	Haemophilia B (IX deficiency)	May–Hegglin thrombocytopenia
	vWD	TAR (thrombocytopenia with absent radii)
	Factor XI deficiency	Bernard Soulier syndrome
	Rarer deficiencies, e.g. V, I	Wiscott–Aldrich syndrome
		Glanzmann's disease
		Other rare abnormalities of platelet adhesion or aggregation

PATTERNS OF BLEEDING

Coagulation disorders, for example haemophilia A or B, usually present with bleeding into joints or muscles, whereas platelet disorders or vasculitic disorders cause more bleeding from mucosal surfaces, e.g. epistaxis, menorrhagia, skin purpura, haematuria. Von Willebrand disease, in which a lack of VWF results in decreased blood levels of factor VIII and failure of platelet aggregation, can present with joint bleeding or mucosal bleeding.

Factor XI deficiency is usually mild in terms of causing joint bleeds but results in post-surgical bleeding of variable severity and does not correlate well with factor XI levels. Often, in retrospect, a history of menorrhagia or mucosal bleeding was present. Factor XIII deficiency causes 'late' severe bleeding postoperatively because the initial clot formed is not properly stabilized, so it breaks down. It usually presents early in life, with prolonged bleeding from the umbilical cord. Whilst deficiencies of all other coagulation factors will be detected by abnormalities of the PT, APTT or TT, in factor XIII deficiency, the usual coagulation screen tests will be normal. However, a fibrin clot solubility test can be done, to show that the clot is more easily soluble than normal. Of note, factor XII deficiency does not cause bleeding. It is often picked up when the APTT is found to be prolonged and it simply needs to be identified to ascertain

that there is not a clinically significant factor deficiency present.

DRUG HISTORY

As part of the clinical history, a drug history should be taken and any drugs which interfere with haemostasis, e.g. nonsteroidal antiinflammatory drugs (NSAID), may need to be stopped.

Diagnostic tests

A full blood count (FBC), PT, APTT and TT will identify most inherited or acquired coagulation factor deficiencies and thrombocytopenias, apart from factor XIII deficiency as above. Further testing should be discussed with a haematologist. A typical algorithm is shown in **Figure 23.3**.

The lupus anticoagulant causes a prolonged APTT *in vitro*, but *in vivo* causes a thrombotic tendency.

If FBC, APTT, PT and fibrinogen results are all normal and a bleeding tendency is still suspected, a platelet dysfunction disorder or vasculitic problem may be present. A bleeding time test can be performed. It would be prolonged in both types of disorder. A

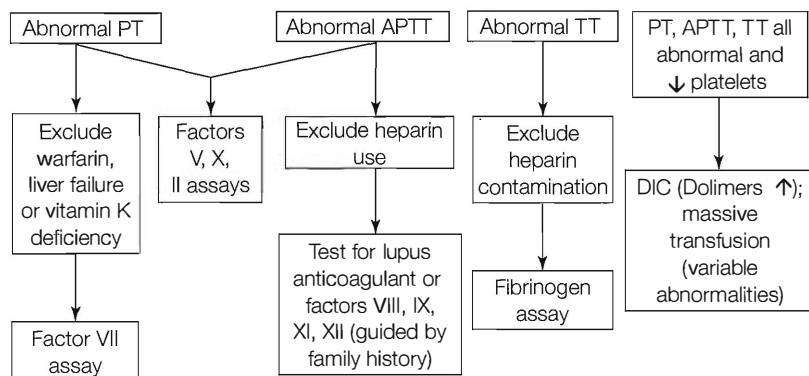

Figure 23.3 Algorithm for managing abnormal coagulation results.

sphygmomanometer cuff is inflated to 40 mmHg around the upper arm and using an automated device a standardized 5-mm incision is made on the forearm avoiding superficial veins and warning the patient about scarring. The incision is blotted every 30 seconds, without disturbing the forming clot and the time taken for bleeding to stop is taken. A normal bleeding time is < 9 minutes. An abnormal bleeding time can indicate a platelet dysfunction problem (congenital or acquired) or a vasculitic problem. Platelet function tests can be performed. These are not routinely available and are done manually on approximately 20 mL of EDTA fresh samples.

Acquired coagulation disorders

LIVER DISEASE

Acute and chronic liver diseases often cause haemostatic abnormalities as the liver is the main site of synthesis of many coagulation and anticoagulant factors. Bleeding most commonly occurs in the upper gastrointestinal tract, from biopsy sites and following surgery. Bleeding into soft tissues is rare.

The PT and APTT are prolonged with a reduction in all coagulation factors, except factor VIII. Platelets may be reduced with alcohol excess.

Treatment

Vitamin K should be given if deficiency is likely. Blood component therapy should only be given when the coagulation screen is abnormal and there is bleeding or an invasive procedure is performed. The outcome should be monitored clinically and by coagulation tests. Fresh frozen plasma (FFP) 12–15 mL/kg contains all of the coagulation factors to replace those deficient in liver disease. Platelets should be given to keep the platelet count greater than $50 \times 10^9/L$: one pool is usually adequate. Inhibitors of fibrinolysis, e.g. tranexamic acid, may be useful. [Grade D]

VITAMIN K DEFICIENCY

Debilitated patients undergoing surgery are particularly vulnerable as broad spectrum antibiotics given in the

context of a dietary deficiency may result in reduced absorption of vitamin K, which is necessary for the synthesis of factors II, VII, IX and X and protein C and S. The PT is prolonged and an injection of i.v. vitamin K is appropriate.

ANTICOAGULANTS

Warfarin inhibits formation of the vitamin K-dependent coagulation factors II, VII, IX and X (and protein C and S) and after stopping warfarin its effects diminish over several days. Heparin potentiates the natural anticoagulant antithrombin and its effects wear off in approximately six hours after stopping unfractionated heparin. Low molecular weight heparins (LMWH) act more specifically to inhibit factor X than as an antithrombin and have a longer half-life than unfractionated heparin. They are useful as they can be given subcutaneously twice a day rather than by continuous i.v. infusion. Protamine sulphate can be used to reverse heparin effects, but it is less effective against LMWH than unfractionated heparin. [*] [Grade C]

Skin necrosis and warfarin

If a patient develops skin necrosis when warfarin is started, protein C or protein S deficiency should be suspected as these are inhibited sooner than coagulation factors. If a patient is already known to have protein C or S deficiency, warfarin should be started under heparin cover and on stopping warfarin, the dose should be tailed off slowly. [*] [Grade C]

Managing patients already on anticoagulation perioperatively

This should be planned and discussed with a haematologist where appropriate at the stage of preassessment clinics or at least well before admission for surgery. National guidelines are available and recommendations are summarized below.²

- For minor surgical procedures, warfarin should be stopped or reduced to achieve a target INR of approximately 2.0 on the day of surgery^{3,4} [**] [Grade B] If the INR is less than 2.5 preoperatively,

surgery can proceed. If the INR is greater than 2.5, the surgeon and haematologist should discuss options.

- Elective surgery could be postponed.
- Warfarin could be reversed using FFP or prothrombin complex concentrate (PCC), but the risks of deferring surgery would have to outweigh the risks associated with FFP or PCC (see Chapter 21, Blood groups, blood components and alternatives to transfusion) to justify using either.
- Surgical opinion may decide that the level of anticoagulation is safe for surgery to take place.
- For dental extraction, oral tranexamic acid mouthwash (4.8 percent) can secure homeostasis while continuing warfarin.⁵ [***] [Grade A]
- For major surgery, oral anticoagulants should be stopped at least three days before surgery. Depending on the degree of thrombotic risk, heparin may be required instead, once the INR is below the therapeutic range – this should be discussed with a haematologist beforehand. [Grade C] The risk of bleeding associated with heparin used in a particular operation should also be considered. When to restart warfarin also depends on the risk of bleeding, but in many instances, warfarin can be started once the patient manages oral intake.
- In all cases, subsequent monitoring of warfarin must be arranged before the patient is discharged.

Managing bleeding and excessive anticoagulation

The risk of bleeding while on warfarin increases significantly when the INR > 5.0, but the decision to reverse warfarin depends on whether there is major or minor bleeding, whether surgery or invasive procedures are urgent. If the patient is warfarinized to prevent thrombi forming on prosthetic heart valves, vitamin K must be used with caution, as it may cause prolonged warfarin resistance and may result in thromboembolism. The degree of reversal must be decided on an individual basis. Recommendations according to national guidelines³ are summarized in **Table 23.3**. Oral vitamin K (5 mg tablets) is quickly and efficiently absorbed so is as effective as i.v. vitamin K, except in patients who have any

condition causing malabsorption of fats. In major bleeding, PCC is preferred where available, as reversal of warfarin is quicker and more effective than with FFP as it can be infused faster. FFP is a suitable alternative if PCC is not available. [Grade C]

Drug interactions

Many drugs interact with warfarin, as listed in the British National Formulary. If a patient is on warfarin any doctor starting, stopping or altering the dose of any other drug should check to see if it will change the anticoagulant effect. It is recommended that if the drug change lasts less than five days and could potentiate anticoagulation, then either no change or a minor reduction may be required. If the drug alteration lasts > 5 days, the INR should be checked shortly after the changes and warfarin adjusted accordingly. [*] [Grade C] Most, but not all, potentiate the effect of warfarin. Correspondingly, warfarin can alter the efficacy of other drugs, e.g. anti-epileptics and oral contraceptives. Apart from drugs which directly affect warfarin metabolism, other drugs which affect haemostasis should be borne in mind, e.g. analgesics with anti-platelet effects, such as aspirin and other nonsteroidal antiinflammatory drugs.

Other anticoagulants

Occasionally, other anticoagulants are used. Thrombolytic drugs, e.g. streptokinase, given for myocardial infarct, within ten days of surgery or invasive procedure, can cause severe bleeding. It may be reversed using aprotinin.

DISSEMINATED INTRAVASCULAR COAGULATION

The coagulation cascade is activated to form clots far beyond the normal restrictions of clot formation local to the site of a vessel injury. There is resultant widespread clot formation and vascular occlusion causing limb and organ damage plus, paradoxically, a bleeding tendency due to depletion of coagulation factors, fibrinogen and platelets. The main underlying causes of disseminated intravascular coagulation (DIC) are as follows:

- severe infections (particularly Gram-negative cocci, e.g. meningococcal septicaemia);

Table 23.3 Recommendations for management of bleeding and excessive anticoagulation.

International normalized ratio	Recommendations	
3.0 < INR < 6.0 (target INR 2.5)	Reduce warfarin dose or stop	
4.0 < INR < 6.0 (target INR 3.5)	Restart warfarin when INR < 5.0	
6.0 < INR < 8.0, no bleeding or minor bleeding	Stop warfarin, restart when INR < 5.0	
INR > 8.0, no bleeding or minor bleeding	Stop warfarin, restart when INR < 5.0. If other risk factors for bleeding give 0.5–2.5 mg of vitamin K (oral)	[**] [Grade B]
Major bleeding	Stop warfarin. Give prothrombin complex concentrate 50 units/kg or FFP 15 mL/kg. Give 5 mg of vitamin (oral or i.v.)	[**] [Grade B]

- shock;
- obstetric disorders (eclampsia, antepartum haemorrhage, amniotic fluid embolism, retained dead foetus);
- severe burns;
- ABO-incompatible transfusion;
- intravascular haemolysis (for example, hypotonic saline, hypotonic fluids after prostatectomy, etc.);
- malignancy (for example, cancer of prostate, pancreas, lung, stomach, usually chronic DIC).

If severe, there is widespread bruising and oozing from venepuncture sites or surgical wounds and mucosal surfaces, for example, epistaxis. There may also be evidence of vascular occlusion in the limbs.

Laboratory tests

Platelets are low; the APTT, PT, TT are prolonged; the fibrinogen level is low and fibrinogen degradation products (e.g. D-dimers) are raised, indicating increased fibrinolysis.

Treatment

In acute DIC, treatment of the underlying condition is crucial. Fresh frozen plasma at 15 mL/kg should be given, and if the fibrinogen is less than 1.0 g/L then one adult dose of cryoprecipitate (from ten donors) should be given. Platelets should be given to keep the platelet count above 50 – so initially one or sometimes two pools of platelets are needed. Subsequent component therapy should be given according to an FBC and coagulation tests repeated 15 minutes after the infusion of the relevant component. Transfusion of red cells may also be needed. There is no conclusive evidence to support the use of antithrombin concentrates, antifibrinolytics or low-dose heparin. Aprotinin may be used where continued bleeding is life-threatening. In chronic DIC, e.g. associated with malignancies, unless there is active problematic bleeding, no treatment is indicated. [Grade C/D]

MASSIVE TRANSFUSION

Levels of coagulation factors and platelet function decline rapidly during storage of blood. The use of 'fresh blood' within 24 hours of collection to overcome this, is not

justified, as testing for viral infections in the donor, for example, human immunodeficiency virus (HIV) and hepatitis B and C, could not be completed. Therefore, when large quantities of stored blood are given in a short time period (for example total blood volume replacement), bleeding may occur. Prolonged hypovolaemia worsens the coagulopathy. Where there are no underlying medical complications, replacement of one adult blood volume (8–10 units of blood) is not usually associated with significant haemostatic problems but these often occur once 1.5–2 times the blood volume has been replaced. There is considerable variation between patients. Therefore, an FBC and coagulation tests help to guide component therapy. Platelets should be kept above $50 \times 10^9/L$ and the PT and APTT kept near to normal and the fibrinogen greater than 1.0 g/L. Microvascular bleeding is typical, e.g. bleeding from mucus membranes and oozing from surgical wounds or catheter sites. It should be noted that dextran can interfere with haemostasis.

ACQUIRED INHIBITORS

These are rare and usually present with unexplained severe and persistent mucosal bleeding (e.g. gastrointestinal tract, genitourinary tract), wound haematomas, massive skin bruises or muscle bleeding. Coagulation tests show a prolonged APTT or PT or TT depending on the coagulation factor affected. The most common is an inhibitor to factor VIII, which may occur secondary to drugs (e.g. penicillin, cephalosporin), rheumatoid arthritis and other connective tissue disorders or post-partum. Management should be discussed with a haematologist.

Inherited coagulation disorders

There may be a family history of haemophilia or VWD or other factor deficiency, or the patient may give a history of excessive bleeding after an operation, invasive procedure or childbirth. If there is an absence of excess bleeding during these procedures, then an inherited coagulation disorder is unlikely. The frequency of inherited bleeding disorders is given in **Table 23.4**.

Table 23.4 Inherited bleeding disorders.

Disorder	Deficiency	Inheritance	Approximate incidence
Haemophilia A	Factor VIII	X-linked	100 per 10^6
VWD	VWF	Autosomal dominant (rarely recessive)	100 per 10^6
Haemophilia B = Christmas disease	Factor IX	X-linked	20 per 10^6
Factor XI deficiency	Factor XI	Autosomal dominant or recessive	5 percent in Ashkenazi Jews, rare in others
Deficiencies of factors X, V, VII, II, I, XIII, V, plus VIII		Autosomal recessive	Each approximately 1 per 10^6

HAEMOPHILIA A AND B

Haemophilia A (due to factor VIII deficiency) is the most common and affects one in 10,000 males. Haemophilia B (due to factor IX deficiency) or Christmas disease is clinically identical, but less common. Both are X-linked disorders, but a third are due to new mutations. Female carriers rarely have a low enough factor level to cause problems, but occasionally, in cases of extreme lyonization, levels may be low enough to warrant treatment before major surgery. Patients with mild forms of haemophilia (factor levels >10 percent) rarely have spontaneous bleeding episodes, but may require treatment before surgery. Severely affected patients (levels less than two percent) may have spontaneous bleeding into joints (particularly weight-bearing joints, e.g. knees) or muscles (of limbs or internally, e.g. psoas muscle haematoma) with associated pain and some severely affected patients have prophylactic treatment with factor concentrate several times per week. Some patients develop inhibitor antibodies in response to treatment with either human or recombinant factor VIII. [*/*]

MANAGEMENT OF HAEMOPHILIA BEFORE SURGERY

Ideally, patients should be treated in a centre experienced in the management of haemophilia. Haemophiliac patients should carry a medical card stating their diagnosis including the level of deficiency and whether inhibitors are present.

ELECTIVE SURGERY

Patients with coagulation factor deficiencies and female carriers of haemophilia A or B, should be assessed well before surgery, ideally at a preassessment clinic. Their management should be discussed with a haematologist and adequate supplies of the relevant coagulation factor arranged. Recommended blood tests are shown in **Table 23.5**. Because the formation of inhibitors is unpredictable, it is important to test for these at preoperative clinic assessments. If present, treatment is far more difficult and needs careful planning. Do not give intramuscular injections to haemophiliacs and avoid using nonsteroidal antiinflammatory drugs. Prophylaxis with heparin or warfarin against thromboembolism is not necessary and can interfere with laboratory monitoring of treatment with the relevant factor.

In mild haemophilia A or VWD, provided there are no contraindications, some procedures can be carried out using an infusion of DDAVP, which raises the level of factor VIII by releasing stored factor VIII. For all other patients with coagulation factor deficiencies an infusion of the relevant factor is needed. The dose, timing and form of concentrate used (whether human or recombinant) should be discussed with a haematologist. Normally, a preinfusion coagulation sample is taken as a

Table 23.5 Blood tests before surgery in haemophiliac patients.

Test	Reason
Baseline factor level	To assess response to treatment
Inhibitor screen	To check if an inhibitor has developed since the last infusion of factor; a different treatment strategy would be required
Virological testing	As factor concentrates before the late 1980s could transmit viral infections
HBsAg and anti-HBs	To determine if a carrier of hepatitis B or if adequately immunized
Anti-HCV	
Anti-HIV	
Full blood count	
Blood group and antibody screen/crossmatch	As appropriate

baseline factor level measurement, then concentrate is infused an hour before surgery and a post-infusion sample is taken to confirm that the factor level has been boosted to well within the normal range (target 80–100 percent). Postoperatively, in severe haemophiliacs an infusion of factor concentrates is required for seven to ten days and patients cannot be discharged quickly after 'minor' surgery. Factor VIII infusions are needed twice a day, but factor IX has a longer half-life so is required once daily. Human derived factor VIII (or IX) concentrates are derived from pools of plasma from thousands of donors and are heat-treated for viral inactivation. Recombinant factor VIII is available and used to some extent, but is very expensive. In addition, tranexamic acid can be useful especially to treat mucosal bleeding, and can be given as a mouthwash (5 percent) for bleeding in the mouth. [Grade C/D]

EMERGENCY SURGERY

This should be discussed promptly with a haematologist. Depending on surgical and haematological considerations, the patient may be best managed by transferring to a hospital with a haemophilia centre, or it may be better to transport supplies of the relevant coagulation factor from a haemophilia centre as soon as possible. When assessing a patient, the exact diagnosis including the level of factor deficiency, needs confirmation either from a card carried by the patient or from the database at the haemophilia centre which cares for them. In a dire emergency where no coagulation factor is available quickly enough, FFP (or cryoprecipitate for factor VIII or fibrinogen deficiencies) may be needed as a holding measure, though it is difficult to raise the levels of factors quickly with FFP alone. The patient or their relatives may

have a supply of the relevant coagulation factor if they are on 'home treatment', i.e. they manage joint bleeds, etc., at home by self-injecting the factor concentrate. Central nervous system bleeding is uncommon, but can occur even after a slight head injury and used to be the most common cause of death in haemophiliacs. Factor treatment must be continued for at least ten days, otherwise late recurrent bleeding can occur. Oropharyngeal bleeding is uncommon, but is clinically dangerous, as extension through soft tissues in the floor of the mouth can cause respiratory obstruction. Laceration of the tongue can be difficult as it cannot be immobilized.

Generally, it is preferable to time the change of wound dressings or physiotherapy after an infusion of factor concentrate, to minimize the risk of bleeding from wounds.

In an untreated haemophilic, bleeding is not so much profuse, as persistent. Clots may initially form, but are bulky and friable and tend to shear off with further bleeding, which may recur over days to weeks. However, this picture is now seen only in haemophiliacs resistant to treatment or in undiagnosed mild to moderate haemophiliacs after their first surgical or dental procedure. If the diagnosis is not known, a coagulation screen and a bleeding history will be required. [**/*]

Acquired platelet disorders

If thrombocytopenia is found without coagulation abnormalities, the patient's history, including a bleeding history, may indicate whether it is a chronic condition or whether the onset is recent. Results of previous platelet counts are useful. Unless surgery is urgent, the cause of the thrombocytopenia should be investigated first, as optimal treatment depends on the underlying cause and platelet transfusions may be contraindicated in some conditions.

INCREASED CONSUMPTION/DESTRUCTION OF PLATELETS

Idiopathic thrombocytopenic purpura (or autoimmune thrombocytopenia)

This is a common condition in which platelets are coated with an autoantibody (usually IgG) resulting in increased platelet destruction in the spleen and thrombocytopenia of variable severity. Idiopathic thrombocytopenic purpura (ITP) may be idiopathic or secondary to other autoimmune diseases, malignancies, drugs (e.g. trimethoprim, sulphonamides, quinidine) especially in children, HIV or viral infections. In adults, ITP may manifest as a single episode, may be recurrent or may cause chronic thrombocytopenia. Treatment is usually with prednisolone or IVIg and a history of a previous good response to these indicates the patient is likely to respond again. Patients who fail to respond long term may require a

splenectomy (and long-term penicillin) or other immunosuppressive agents. Treatment prior to any surgical procedure depends on the starting platelet count and the nature of the surgery. For most major surgery, the platelets should be kept above 50; for central nervous system (CNS) and eye surgery platelets should be kept above 100. For minor surgery it is not necessary to keep platelets above 50. If treatment is required, steroids or IVIg can be given, but the response may take up to a week to achieve, so planning in advance is essential. In an emergency, giving platelet transfusions is not indicated except where there is life-threatening bleeding, e.g. CNS bleeding, as the platelets transfused are consumed very rapidly. In this setting, IVIg 1 mg/kg before platelet transfusion may be of benefit. [Grade D]

Thrombotic thrombocytopenia and haemolytic uraemic syndrome

The thrombotic microangiopathies are a spectrum of clinical syndromes characterized by microangiopathic haemolytic anaemia, thrombocytopenia, microvascular thrombosis and multiple organ failure. Thrombotic thrombocytopenia occurs in one per million of the population per year and presents with fever, intravascular haemolytic anaemia, thrombocytopenia, renal failure and neurological deficits. It may be acute, chronic or recurrent and may be associated with systemic lupus erythematosus (SLE), other connective tissue diseases, pregnancy or HIV. Haemolytic uraemic syndrome presents with haemolytic anaemia, thrombocytopenia and renal failure and may be associated with a viral or gastrointestinal infection (especially in children) or HIV. The mechanisms of these are not well understood, but are believed to involve vascular endothelial injury resulting in abnormal clumping of platelets and microvascular thrombosis. In thrombotic thrombocytopenia (TTP), it is proposed that there is a deficiency in the patient's plasma of a factor that normally inhibits platelet aggregation. This concurs with the finding that the most effective treatment is plasma infusion or exchange. It should be noted that these disorders cause thrombosis rather than bleeding, but are important to include in the differential diagnosis of thrombocytopenia.

Diagnosis

Once the possibility of haemolytic uraemic syndrome (HUS) or TTP has been considered, a blood film will show fragmented red cells and reduced numbers of platelets. A coagulation screen will be normal and urea and electrolytes are often abnormal.

Treatment

Platelet transfusions are normally contraindicated, as they may worsen the condition and result in death. Plasma exchange is optimal for TTP, giving an 80 percent response rate. It is less effective in HUS, but sometimes FFP infusions alone may be helpful. [Grade C/D]

Post-transfusion purpura

This is an uncommon condition in which the patient has a sudden dramatic fall in platelet count (less than $10 \times 10^9/L$) about five to ten days after a transfusion. They have purpura, mucosal bleeding and bleeding from surgical wounds. It is more common in women, as it is due to an antiplatelet antibody which formed after previous exposure to platelet antigens, usually from a foetus during pregnancy. In men, previous transfusion is the source of platelet antibody sensitization. The mechanism of post-transfusion purpura (PTP) is not well understood as the anti-HPA 1a antibody destroys any transfused platelets which are HPA 1a-positive, but also destroys the patient's own platelets which are HPA 1a-negative.

Diagnosis

A blood film is normal apart from low numbers of platelets, and the coagulation screen is normal. Anti-HPA 1a antibodies are found (results may take several days). Postoperatively, the differential diagnosis often includes heparin-induced thrombocytopenia (see below).

Treatment

Thrombocytopenia may resolve after a couple of weeks, but this is variable and the risk of significant bleeding during that time is high. Therefore, IVIg is given to minimize the duration of thrombocytopenia. Platelet transfusions are ineffective. Future transfusions should ideally be avoided, as even small amounts of platelets in red cell transfusions can precipitate an episode, but if needed, special components can be provided. [Grade D]

Heparin-induced thrombocytopenia with thrombosis

Type 1 heparin-induced thrombocytopenia is common and benign. The platelet count falls early after heparin is started and is not severe. Heparin-induced thrombocytopenia with thrombosis (HITT) type 2 is potentially lethal, and although it does not cause bleeding, it is crucial to consider in the differential diagnosis of thrombocytopenia after surgery, as heparin must be stopped. It is due to development of a platelet activating autoantibody against the heparin-platelet factor 4 complex. It presents five days or more after heparin is started and thrombocytopenia may be moderate to severe. Thrombosis causes occlusion of major vessels (sometimes while the platelet count is falling but still within normal range) and is fatal in 30 percent. Sometimes DIC and skin necrosis occur at the site of subcutaneous injections. HITT type 2 is much less common with low molecular weight heparin compared to unfractionated heparin.

Diagnosis

After starting heparin, the platelet count must be monitored beyond the fifth day and a high index of suspicion is needed. A PF4/heparin enzyme-linked immunosorbent assay (ELISA) test is available.

Treatment

Heparin must be stopped whenever HITT type 2 is suspected. Instead, the heparinoid 'orgaran' or warfarin can be used. Platelets are contraindicated. [Grade D]

Splenomegaly

Splenomegaly may result in thrombocytopenia due to pooling of platelets in the spleen.

REDUCED PRODUCTION OF PLATELETS

Conditions resulting in failure of production of megakaryocytes in the bone marrow are less common than conditions due to increased consumption. They include leukaemias, aplastic anaemia, myelodysplasia, systemic chemotherapy and metastatic infiltration by carcinomas. Severe thrombocytopenia may present with mucosal bleeding. A history of other symptoms and signs will aid diagnosis and a full blood count and blood film followed by a bone marrow examination if appropriate can elucidate the cause.

Treatment

Unless the patient is bleeding or requires an invasive procedure, platelet transfusions are only required when the platelet count is less than 10 (or <20 if the patient has sepsis or a coagulopathy). Platelets should be kept >50 for major surgery, lumbar punctures, liver biopsy or insertion of a central line, but >100 if eye or CNS surgery is performed.⁶ [**] [Grade B] Tranexamic acid may also be useful.

PLATELET DYSFUNCTION

Drugs

NSAID act by inhibiting the cyclooxygenase pathway in platelets and therefore inhibit production of thromboxane A_2 , which is required for platelet aggregation. To reverse the effects of aspirin, and other NSAID, they should be stopped five days before surgery. Specific antiplatelet drugs are also used in some patients, e.g. with ischaemic heart disease.

Extracorporeal circuits

Cardiopulmonary bypass and other extracorporeal circuits (ECC) result in platelet dysfunction through a number of mechanisms including a reversible depression of TXA_2 by hypothermia, fragmentation and loss of platelet surface receptors due to sheer stress, turbulent blood flow and adhesion to foreign surfaces. Heparinization of ECC should be adequately reversed when use of the circuit is stopped. Platelet function normally corrects itself by three hours after cardiac bypass. Platelets are not routinely indicated, unless antiplatelet drugs are also in use.

Renal failure

Uraemia may cause defective platelet–vessel wall interaction, but the most important factor in causing bleeding is the low haematocrit associated with chronic renal failure. Transfusion or administration of erythropoietin to raise the haematocrit (Hct) to greater than 0.30 usually corrects the bleeding tendency. DDAVP may also be useful in lessening bleeding, by increasing release of VWF to overcome a VWF inhibitor sometimes present in renal failure, with shortening of the bleeding time for about four hours afterwards. These measures may allow surgery to take place with a reduced risk of bleeding. [Grade D]

Inherited platelet disorders

These are rare and include a range of disorders of platelet function and thrombocytopenias. Bernard Soulier syndrome is due to a defect in platelet glycoprotein Ib which causes defective platelet adhesion to vessel subendothelium, with mucocutaneous bleeding, which is sometimes severe. The platelet count is mildly reduced and the platelets are large and abnormal. Glanzmann’s disease is due to a defect in the platelet glycoprotein complex IIb/IIIa, so that platelet aggregation is impaired. The platelet count is normal. Skin and mucous membrane bleeding, especially in the nasopharynx, are common. In May–Hegglin thrombocytopenia, platelet numbers are often markedly reduced and the platelets are giant. The diagnosis of each is made based on a FBC, blood film and platelet aggregation followed by immunological tests to measure levels of glycoproteins studies where needed.

TREATMENT

Patients should avoid the risk of trauma where possible. There is no prophylactic treatment for spontaneous bleeding, but patients should avoid drugs which affect platelet function, e.g. NSAIDs. For bleeding episodes, local measures are often successful, so that platelet transfusions are not often needed. Arterial embolism has been used effectively for severe epistaxis. Ideally, platelet transfusions should be HLA-matched in order to prevent HLA antibody formation and platelet refractoriness in these patients. Specific blood donors would need to be called, once the patient’s HLA type is known, so this should be arranged several weeks in advance. [Grade D]

THROMBOTIC DISORDERS

Management of a thrombotic episode

The pathogeneses of venous and arterial thrombosis are different and a patient’s predisposition to either depends

on a combination of environmental or acquired and inherited factors. Stasis is a prominent factor in venous thrombosis, whereas damage to the vascular endothelium is central to arterial thrombosis. Acquired and inherited risk factors for venous and arterial thrombosis are given in Tables 23.6, 23.7 and 23.8.

TREATMENT OF A NEW DEEP VEIN THROMBOSIS OR PULMONARY EMBOLISM

According to local hospital practice, deep vein thrombosis (DVT) and pulmonary embolism (PE) may be treated with an i.v. infusion of unfractionated heparin, which requires monitoring, aiming for an APTR of 1.5–2.5; or using LMWH given subcutaneously once or twice daily (depending on the individual product) using a weight-based dose.

REFERRAL FOR INVESTIGATION OF THROMBOPHILIA

The majority of thrombotic episodes have no obvious underlying cause, but it is worth referring a patient for investigation if thromboses are recurrent, there is a family history, or there are unusual features, e.g. young age, unusual site, etc. They may have a ‘thrombophilia’, i.e. an inherited or acquired disorder which predisposes them to thrombosis. Interpretation of laboratory tests for these is difficult while the patient is on anticoagulants or in the acute phase of a thrombotic episode. Testing is best performed when anticoagulants have been stopped for at least one month.⁷ [Grade D]

Table 23.6 Acquired risk factors for venous thromboembolism.

Risk factor
Immobility
Dehydration
Tissue trauma, including surgery
Myocardial infarction
Pregnancy and puerperium
Oestrogens
Obesity
Varicose veins
Previous deep venous thrombosis
Congestive cardiac failure
Malignancy
Nephrotic syndrome
Advancing age
Hyperviscosity states
Connective tissue diseases (especially lupus anticoagulant)
Behcet’s syndrome
Paroxysmal nocturnal haemoglobinuria
Myeloproliferative disorders
Therapy with coagulation factor concentrates containing activated factors (II, IX, X concentrates)

Table 23.7 Genetic risk factors for venous thromboembolism.

Risk factor	
Deficiency of anticoagulant	Antithrombin
	Protein C
	Protein S
Abnormal protein	Factor V Leiden
	Dysfibrinogenaemia
Increased procoagulant	Prothrombin
	Factor VIII
Abnormal metabolism	Homocystinuria
Putative mechanisms	Thrombomodulin defects
	Fibrinolytic defects

Table 23.8 Acquired and genetic risk factors for arterial arterothrombosis.

Risk factor	
Increased procoagulant	Fibrinogen
	Factor VII
	Factor VIII
Abnormal metabolism	Hypercholesterolaemia
	Diabetes
	Hyperhomocysteinaemia
Autoimmune disease	Antiphospholipid antibodies
Environmental	Smoking
	Diet

PERIOPERATIVE MANAGEMENT

Whether to treat patients with thrombophilia any differently from other patients depends on a number of factors including their diagnosis, history of thrombosis and nature of surgery and should be discussed with a haematologist. National guidelines recommend that:⁷

- All patients with a previous DVT (with or without a thrombophilic defect) receive prophylactic anticoagulation to cover surgery, trauma or immobilization including plaster casts. Equally, so should patients who are known to have a thrombophilic disorder, have had no thrombotic episode themselves, but have a relative with the same disorder who has had a thrombosis. [Grade C]
- There is no evidence that the dose or duration of anticoagulation should be different in patients with a thrombophilia than other patients, except that patients with antithrombin deficiency may require larger doses of heparin.

Heparin is required for four to five days (with no monitoring required), but should be continued until the oral anticoagulant warfarin achieves a therapeutic level, as monitored by the INR. The recommended warfarin loading schedule for different conditions and target INRs are given in **Table 23.9** and in the Haemostasis and

Table 23.9 Warfarin loading schedule.

Day	INR	Warfarin dose (mg)
First	<1.4	10
Second	<1.8	10
	1.8	1
Third	>1.8	0.5
	<2.0	10
	2.0–2.1	5
	2.2–2.3	4.5
	2.4–2.5	4
	2.6–2.7	3.5
	2.8–2.9	3
	3.0–3.1	2.5
	3.2–3.3	2
	3.4	1.5
Fourth	3.5	1
	3.6–4.0	0.5
	>4.0	0
		(Predicted maintenance dose)
	<1.4	>8
	1.4	8
	1.5	7.5
	1.6–1.7	7
	1.8	6.5
	1.9	6
	2.0–2.1	5.5
	2.2–2.3	5
	2.4–2.6	4.5
	2.7–3.0	4
	3.1–3.5	3.5
	3.6–4.0	3
	4.1–4.5	Miss out next day's dose then give 2 mg
	>4.5	Miss out 2 days' doses then give 1 mg

Thrombosis Task Force for the British Committee for Standards in Haematology's Guidelines on Oral Anti-coagulation.² Patients should have the dose and side effects of warfarin explained to them and be referred for subsequent monitoring of warfarin. [Grade B]

Perioperative heparin prophylaxis for high risk patients

For patients at high risk of venous thromboembolisms, unfractionated or LMWH heparin may be used according to local hospital practice, subcutaneously 5000 units twice or three times a day starting two hours preoperatively and continuing until the patient is mobile.

ORAL CONTRACEPTIVES

Because of the increased risk of venous thromboembolism associated with oestrogen-containing contraceptives around the time of surgery, these should be stopped (and adequate alternative arrangements made) at least

four weeks before major elective surgery, including surgery to the legs or any surgery resulting in prolonged immobilization of the legs. It can be resorted to at least two weeks after full mobilization, when the first period occurs. However, oral contraceptives need not be stopped for minor surgery involving a short anaesthetic, e.g. dental extractions. For major surgery, if stopping oestrogen-containing oral contraceptives in advance is not an option, heparin prophylaxis is indicated.

Inherited and acquired thrombophilias

ACQUIRED

The pathogenesis of thrombosis is often multifactorial. Tissue trauma, whether surgical or accidental, and malignant disease both predispose patients to venous thromboembolism, though the exact mechanisms are poorly understood. Myeloproliferative disorders (e.g. polycythaemia rubra vera and essential thrombocythaemia), hyperhomocysteinaemia and Behçet's syndrome predispose patients to both venous and arterial thromboembolism. The primary antiphospholipid syndrome also predisposes to both venous and arterial thromboembolism. The lupus anticoagulant is only one of the antiphospholipid antibodies which can predispose to thromboembolism, so for screening purposes, 'antiphospholipid antibodies' rather than the lupus anticoagulant should be requested.

INHERITED

Antithrombin, protein C and protein S deficiency are all usually autosomal dominant conditions: rare homozygous individuals are usually very severely affected almost from birth. All predispose to venous thromboembolism often at an early age (<45 years). However, the more recently discovered factor V Leiden variant, which is present in 4 percent of Caucasians, is the most common cause of early onset venous thrombosis. Raised factor VIII levels are also associated with increased venous thrombosis. [***/**]

If thrombophilia is suspected, referral for further investigation should be discussed with a haematologist.⁷

KEY POINTS

- Patients with abnormal PT, APTT, TT or platelet count should be investigated on the basis of their medical history.
- Elective surgery on patients taking warfarin needs advanced planning to minimize the risk of bleeding or thrombosis, with the minimum use of blood components.

- Surgery in haemophilic patients needs planning in advance to ensure adequate factor therapy and an adequate response.
- Patients with thrombocytopenia should be discussed with a haematologist, to ensure the optimal treatment depending on the underlying cause and to avoid the use of platelets in conditions where this is contraindicated.

Best clinical practice

- ✓ Haemophiliacs: do not give intramuscular injections or nonsteroidal antiinflammatory drugs, or routine heparin prophylaxis.
- ✓ Haemophiliacs: in central nervous system bleeding, e.g. following head injury, factor replacement treatment must continue for at least ten days, or later bleeding recurs.

Deficiencies in current knowledge and areas for future research

- Further studies are needed towards optimal antiplatelet agents.
- Further work is needed to understand more fully the causes of thrombophilia.
- Further work towards an optimal anticoagulant agent, taken orally, with minimum side effects and with minimum monitoring required, is needed.

Physiology of the hypothalamus and pituitary gland	300		

SEARCH STRATEGY AND EVIDENCE-BASE

This chapter was prepared from anatomy and physiology texts and supported by a Medline search using the key words anatomy, pituitary and cavernous sinus. The anatomical studies quoted constitute level 3 evidence.

ANATOMY

Embryology

The adenohypophysis is derived from the placodal ectoderm of the roof of the stomodeal. The neurohypophysis is derived from an evagination of the floor of the forebrain and the third ventricle.

There is a saccular depression in the roof of the stomodeum immediately in front of the oropharyngeal membrane. This saccular depression evaginates to form the pouch of Rathke. This area remains in close contact with the ventral surface of the forebrain. The pouch of Rathke develops into the adenohypophysis. The anterior part becomes the pars anterior and the posterior part, in contact with the forebrain, becomes the pars intermedia. The section of the forebrain in close contact with the pars intermedia becomes the neurohypophysis (see **Figure 24.1**).¹ In foetal life and childhood, the vestige of Rathke's pouch remains as the hypophyseal cleft separating the pars anterior and pars intermedia. The pars intermedia is rudimentary in humans and is of little functional significance. Remnants of Rathke's pouch may persist below the sphenoid in the roof of the nasopharynx forming a pharyngeal pituitary. The clivus and

the dorsum sellae of the future sphenoid bone are formed from mesenchymal condensations surrounding the hypophysis. The cavernous sinus is derived from the primary head vein (see **Figure 24.1**).

PITUITARY GLAND

The pituitary gland or hypophysis cerebri is an ovoid body measuring approximately 8 mm in the anteroposterior diameter by 12 mm transversely by 4 mm high. By the age of puberty it weighs approximately 100–500 mg. It doubles in size during pregnancy and usually remains larger in females. The adenohypophysis constitutes two-thirds of its volume.

There are two major parts to the hypophysis:²

- adenohypophysis: includes the pars anterior, pars intermedia and pars tuberalis;
- neurohypophysis: includes the pars posterior, infundibular stem and median eminence.

Both these parts include parts of the infundibulum and are preferred to the old terms anterior and posterior lobes (see **Figure 24.2**).

Figure 24.1 Embryological development of the hypophysis.

Figure 24.2 Lateral view of the hypophysis in the sella turcica with the intercavernous venous sinuses demonstrated (blue).

Adenohypophysis

This structure is highly vascular and consists of epithelial cells arranged in follicles and cords between thin walled vascular sinuses. This arrangement is supported by a delicate skeleton of reticular tissue.

Pars tuberalis contains a large number of blood vessels as well as the secreting cells listed above. In some species this area is rich in receptors for the pineal hormone melatonin.

Traditionally, cell types of the adenohypophysis have been divided up by their staining characteristics into chromophil (acidophilic, basophilic) and chromophobe cells. Modern immunohistochemical techniques allow us to identify cells by the hormones that they produce as follows:

- somatotrophs: (acidophilic) the largest and most abundant chromophil cells these secrete the protein somatotrophin or growth hormone (GH);

- **mammotrophs:** (acidophilic) secrete the polypeptide hormone prolactin (PRL) and become the dominant cell during pregnancy and lactation;
- **mammotrophs:** (acidophilic) secrete growth hormone and prolactin simultaneously;
- **corticotrophs:** (basophilic) produce the precursor molecule pro-opiomelanocorticotropin, which is broken down into adrenocorticotropin (ACTH), beta-lipotropin and beta-endorphin;
- **thyrotrophs:** (basophilic) secrete thyroid-stimulating hormone (TSH);
- **gonadotrophs:** (basophilic) secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH);
- **chromophobe cells:** these small cells form the majority of the cells in the adenohypophysis. They include stem cells and degranulated secretory cells;
- **folliculostellate cells (FS):** these are the supporting cells of the adenohypophysis, with growth factor and cytokine activity. Their expression of cytokeratins supports the theory that the adenohypophysis is derived from Rathke's pouch.³

Neurohypophysis

Axons with their cell bodies in the supra optic and paraventricular nuclei of the hypothalamus run to the neurohypophysis. Some terminate in the median eminence from where they can influence the action of the adenohypophysis (see below), others run down through the stalk of the hypophysis to the main mass of the neurohypophysis where they terminate close to the sinusoids. The latter transport polypeptide hormones in conjunction with a glycoprotein (neurophysin) to the neurohypophysis where they are stored prior to release. The two hormones secreted in this way are:

1. antidiuretic hormone (ADH) or vasopressin;
2. oxytocin.

BLOOD SUPPLY OF THE HYPOPHYSIS

The arterial supply of the hypophysis is from single inferior hypophyseal arteries and several superior hypophyseal arteries on each side, all of which are branches from the internal carotid. The superior hypophyseal arteries supply the median eminence and the infundibulum. The inferior hypophyseal arteries anastomose to form an arterial ring around the infundibulum, which gives fine branches supplying the capillary bed of the neurohypophysis. The adenohypophysis does not have a direct arterial supply⁴ but is supplied by long and short portal vessels, which run from the median eminence and the lower infundibulum, respectively, to the capillary bed of the adenohypophysis (Figure 24.3).

The hormones of the adenohypophysis are secreted by exocytosis into the nearby sinusoids. The major signal for this secretion involves the release of specific releasing factors from neurones in the median eminence, which are then transported to the adenohypophysis by the portal system.

The venous drainage of the hypophysis is less clear but has important implications in understanding the control of pituitary hormone secretion.⁴ Possible drainage is via:

- long and short portal vessels to the infundibulum;
- large inferior hypophyseal veins into the dural venous sinuses;
- to the hypothalamus via the median eminence;
- reversible flow between the adenohypophysis and neurohypophysis.

Pituitary gland capsule

The gland has a capsule which is made up of very dense fibrous tissue, which is in continuity with the fibrous connective tissue of the gland. The gland appears to be loosely attached to the surrounding connective tissue, which forms a smooth nest for the hypophysis. Bridging veins, capsular arteries and fibrous bundles cross this space.⁵

THE SELLA TURCICA

The sella turcica, or Turkish saddle, is the deep depression in the body of the sphenoid bone. It contains the hypophysis cerebri, dural layers and the inter-cavernous sinuses. The hypophysis fills 50 to 85 percent of the fossa.⁶

The bony landmarks around the fossa are as follows (see Figure 24.4).

- **Optic canal.** Between the roots of the lesser wing and the body of the sphenoid medially. Descends slightly anterolaterally, contains the optic nerve, ophthalmic artery and meninges.
- **Anterior clinoid process.** This is the posterior projection from the lesser wing of the sphenoid.
- **Tuberculum sellae** is a midline ridge in the anterior slope of the sella tunica.
- The **dorsum sellae** is the posterior wall of the sella turcica, the superiolateral projections of the dorsum form the posterior clinoid processes.
- The **groove** for the internal carotid artery is formed as the artery turns anteriorly from the foramen lacerum. The groove can be seen on the sphenoid lateral to the sella turcica.
- The **middle clinoid process** is a small elevation in the median edge of the groove. In approximately 10 percent of skulls the middle and anterior clinoid processes are joined to form a continuous ring called the carotico-clinoid foramen.⁷
- The **lingula** is a small projection arising on the posterolateral aspect of the carotid groove.
- The **clivus** is made up of the body of the sphenoid bone behind the dorsum sellae and the basioccipital bone. The upper part of the pons lies adjacent to the clivus.

In approximately 2 percent of skulls there is a bony bridge joining the anterior clinoid and posterior clinoid processes called the tinea interclinoidea. In approximately 1 percent of skulls there is a bony projection in the floor of the sella called the sella spine. It is a bony spicule that projects from the junction of the anterior and inferior walls of the sella towards the middle of the hypophyseal fossa. It is usually 1 mm in diameter and 2–5 mm in length. It probably represents an ossified remnant of the notochord.^{6,8}

Dural reflections

The diaphragmatica sella is a sheet of dura mater that forms the roof of the sella turcica. This small flat horizontal circular sheet covers over the fossa between the clinoid processes and is continuous with the roof of the cavernous sinus. There is a central defect in the diaphragm called the ‘foramen diaphragmatis’ which the pituitary stalk or infundibulum passes through. It is of variable diameter up to 5 mm.⁹ In the region of the foramen of the dura, arachnoid and pia mater fuse with each other and with the capsule of the pituitary gland to form one fibrous layer that lines the hypophyseal fossa. In the fossa it is not possible to differentiate the fibrous layers and there are no subdural or subarachnoid spaces. Therefore, there is no cerebrospinal fluid (CSF) in the normal pituitary fossa. The diaphragmatica sella separates the contents of the pituitary fossa from the CSF. In the region of the foramen, the barrier may be very thin and consist of only arachnoid mater.¹⁰

The tentorium cerebelli is the main dural sheet that loops around the brainstem and separates the cerebral hemispheres from the cerebellum, forming the floor of

Figure 24.4 Postero-superior view of the sella turcica of a skull. The position of the right internal carotid is demonstrated.

the middle cranial fossa. It arises from the anterior clinoid processes and has a 'U' shaped free border looping posteriorly. The peripheral attachments of the tentorium run from the anterior clinoid process backwards as a ridge of dura mater to the apex of the petrous temple bone. This ridge is at the junction of the roof and the lateral part of the cavernous sinus. From here, the attachment runs backwards to the posterior clinoid process forming the roof of the cavernous sinus and is continuous with the diaphragmatica sella. The remainder of the peripheral attachment of the tentorium is to the superior surface of the petrous temporal bone in the region of the superior petrosal sinus and to the occipital bone in the region of the transverse sinuses.

The cavernous sinus

These sinuses lie on the lateral aspect of the sphenoid body and are the lateral relations of the sella turcica. The term cavernous was adopted when it was thought that these sinuses were a single cavern with a few trabeculae. More recent work using corrosion casts has established that these sinuses are plexiform in nature, i.e. they are made up of an intertwined network of thin walled venous channels of varying sizes that divide and coalesce and incompletely surround the carotid arteries.¹¹

The sinuses are approximately 1 cm wide and up to 2 cm long. They extend forwards from the apex of the petrous temporal bone to the superior orbital fissure. They are wider at the roof than at the base. The carotid arteries have a variable course in the sinuses. They enter postero-inferiorly, having passed through the carotid canal, and then turn anteriorly passing horizontally through the sinus before turning superiorly to enter the anterior cranial fossa medial to the anterior clinoid processes. The horizontal portion of the artery is usually the lateral relation of the hypophysis. There is significant individual variation and the artery may be up to 7 mm away from the gland with the intervening space filled with venous plexus, or it may be as close as 1 mm to intervening venous tissue.¹²

The oculomotor nerve, trochlear nerve and ophthalmic division of the trigeminal nerve are closely related to, but not in the lateral wall of the sinus as they pass anteriorly towards the superior orbital fissure.¹² The abducens nerve runs inferiolaterally to the carotid artery in its horizontal portion. The sympathetic plexus runs with the carotid artery.

The sinus receives tributaries from the superficial middle cerebral vein, inferior cerebral vein, sphenoparietal sinus, inferior ophthalmic vein and sometimes the central retinal vein and frontal tributaries of the middle meningeal vein. The sinus then drains into the internal jugular vein via the inferior petrosal sinus to the transverse sinus via the superior petrosal sinus, and small emissary veins drain through the foramen lacerum and ovale to the pterygoid plexus.²

Intercavernous venous sinuses

The two cavernous sinuses are connected across the floor of the pituitary fossa by the intercavernous venous sinuses. Some texts indicate that there is a single anterior and single posterior vein in the floor of the fossa, hence the old term 'inferior circular sinus of Winslow'. Cast studies have shown that the arrangement is much more variable with multiple interconnections across the floor possible. The superior and inferior connections may be found behind the anterior wall of the fossa and the connections may widen out laterally as they enter the cavernous sinuses (see **Figure 24.1**).¹³

Relations of the pituitary fossa

• Superior:

- the diaphragmatica sella;
- the pituitary stalk and infundibulum;
- the optic chiasm anterior to the infundibulum 5–10 mm above the diaphragm;
- anterior cerebral artery and anterior communicating artery anterior to the optic chiasm;
- internal carotid artery/middle cerebral artery lateral to the infundibulum;
- CSF surrounds the above structures above the diaphragmatica sella;
- the third ventricle lies above the infundibulum.

• Posterior:

- Lamellar bone of the dorsum sella behind which is the dura mater of the poster fossa behind which is the basilar artery;
- CSF.

• Lateral:

- upper part of the cavernous sinus containing
 - horizontal portion of the internal carotid artery
 - oculomotor, trochlear and abducens nerves.

The lateral wall of the cavernous sinus is a thick sheet of dura mater, the medial wall is much thinner. There is no thick dural sheet and the capsule of the pituitary is the only barrier against spread of adenoma from the pituitary fossa.⁶

• Anterior and inferior:

- sphenoid sinus;
- intrasphenoid sinus septum.

The anterior wall of pituitary fossa usually forms an angle of 90° with the roof of the sphenoid sinus or planum sphenoidale, although this angle may become more acute if fossa is expanded by a pituitary adenoma.¹⁴

The degree of pneumatization of the sphenoid is variable. In 88 percent pneumatization, aeration of the sinus extends posteriorly at least as far as the posterior limit of the pituitary fossa. In 10–12 percent, the sinus extends to the

anterior wall of the pituitary fossa and in less than 1 percent the pituitary sinus is not pneumatized.¹⁴

The intrasphenoid sinus septae are thin, variable sheets of bone that have significant anatomical importance to the pituitary surgeon. If it is in contact with the anterior wall of the sphenoid, the septum is usually in the midline at this point, i.e. in a plane continuous with the nasal septum. The intrasphenoid sinus septum remains in the midline and attaches to the anterior wall of the pituitary fossa in 41.9 percent. In the remainder it deviates laterally where it may insert over the internal carotid artery. In addition, 20 percent of sphenoids have an additional intrasphenoid sinus septum running parasagittally. These septae are usually deficient anteriorly and, again, often insert posteriorly over the internal carotid artery.¹⁴

PHYSIOLOGY OF THE HYPOTHALAMUS AND PITUITARY GLAND

The hypothalamus and the pituitary act as a functional unit representing the main interface between the endocrine system and the nervous system. The hypothalamus controls the secretion of hormones from both the adenohypophysis and neurohypophysis. The secreted hormones, in turn, influence the hypothalamus by negative feedback loops.

Hypothalamic hormones

The following are secreted directly by the hypothalamus and the median eminence and influence the adenohypophysis via the portal system.¹⁵

- Growth hormone releasing hormone (GHRH). Causes release of growth hormone. Cell bodies in arcuate nuclei.
- Somatostatin. Inhibits secretion of GH and TSH. Cell bodies in periventricular region.
- Dopamine. Inhibits PRL secretion via portal system. PRL secretion is predominantly inhibitory; therefore disruption of the hypothalamus/pituitary connection results in hyperprolactinaemia. This is often seen in nonsecreting pituitary adenomas.
- Thyrotropin-releasing hormone (TRH). Stimulates release of TSH.
- Corticotropin-releasing hormone (CRH). Stimulates the release of ACTH and its precursor pro-opiomelanocorticotropin. Cell bodies in the paraventricular nuclei together with TRH releasing neurones.
- Gonadotropin-releasing hormone (GnRH). Cell bodies in the optic area. Stimulates release of both LH and FSH.

Neurohypophyseal hormones

These two hormones are both nonopeptides. They are transported down the axons from the cell bodies in the supraoptic and paraventricular nuclei bound to neurophysin.

ADH, or arginine vasopressin, regulates water balance and is a potent vasoconstrictor in hypovolaemic shock.

Oxytocin causes contraction of smooth muscle, particularly the myoepithelial cells lining the mammary gland ducts.

Adenohypophyseal hormones

ACTH

Circulating levels

ACTH has a half-life of only 7–12 minutes and is secreted episodically. Its plasma concentrations and those of cortisol therefore fluctuate greatly.

Tests for ACTH deficiency

The diurnal rhythm results in a wide variation in levels of ACTH and cortisol throughout the day. Single samples, even when taken at a fixed time (e.g. early morning cortisol) are therefore only an approximate guide. The hypothalamic-pituitary-adrenal axis can be tested by the following.

- ACTH stimulation. Plasma cortisol levels are measured in response to an injection of synthetic ACTH. This tests the adrenal glands ability to respond to ACTH.
- Insulin-induced hypoglycaemia. Hypoglycaemia stimulates the production of CRH, then ACTH and finally cortisol, which can be measured reliably.
- Metyrapone stimulation test. Metyrapone blocks the conversion of cortisol from its precursor 11-deoxy cortisol. In the presence of the normally functioning axis it leads to a drop in cortisol secretion, an increase in CRH, ACTH and 11-deoxycortisol levels, the last of which can be reliably measured in circulation.

Effects

Stimulates the adrenal cortex to secrete glucocorticoids, mineralocorticoids and androgenic steroids. The hyperpigmentation seen in excess ACTH secretion states (Addison's disease, Nelson's syndrome) is due to ACTH binding to MSH receptors.

Control of secretion

CRH stimulates secretion in a diurnal rhythm with the peak for waking and a gradual decline through the day. There is also an increase in ACTH secretion in response to stress, which can be emotional, physical or biochemical.

Cortisol acting on the hypothalamus and the pituitary levels provides negative feedback.

GROWTH HORMONE

Circulating levels

The half-life of growth hormone is 20–50 minutes. Normal early morning levels are 0–40 µg/L. Insulin-like growth factor (IGF)-1 levels are less variable and are age and sex related, but are better indications of growth hormone levels.¹⁶

Effects

Its main function is to promote growth. This action is mediated by the IGF-1, which increases protein synthesis and fat metabolism for energy production. It counteracts the effects of insulin, impairing glucose uptake into cells.

Control of secretion

This is mediated by GHRH (stimulation) and somatostatin (inhibition). Somatostatin analogues are being increasingly used in the treatment of acromegaly. Peak levels of growth hormone occur one to four hours after the onset of sleep and this is when the majority of growth hormone is produced. Less growth hormone is secreted with advancing age. Levels are increased by exercise, physical, metabolic and emotional stress. Decreased levels are seen in children with severe emotional deprivation.

Tests of growth hormone secretion

- Insulin-induced hypoglycaemia: in normal individuals hypoglycaemia will result in an increase in growth hormone levels and is easily measured. This response may be lacking in individuals with growth hormone deficiency.
- Glucose tolerance test: increased circulating glucose level lowers growth hormone levels in normal subjects but not in acromegals and therefore this test is useful in the diagnosis of acromegaly.

PROLACTIN

Circulating levels

The half-life is 50 minutes. The normal range is less than 20 µg/L.¹⁶

Effects

Prolactin stimulates lactation. During pregnancy, oestrogen together with progesterone and cortisol help promote breast development. Prolactin levels increase during pregnancy but the high levels of oestrogen inhibit lactation. The oestrogen and progesterone levels fall at parturition and the high prolactin levels then stimulate lactation. Prolactin does not have a role in the development of normal breast tissue.

Prolactin does not affect gonadal function physiologically but in hyperprolactinaemia gonadal function is affected. There is shortening of the luteal phase of the cycle in women with failure of ovulation, amenorrhoea and infertility. Men develop decreased testosterone production, decreased libido, impotence and infertility.

Control of secretion

Peak secretion is usually between 4 and 7 a.m. and is episodic.

Increased secretion is seen following physical stress, surgery, nipple stimulation, hypoglycaemia and myocardial infarction.

Prolactin secretion is predominantly controlled in an inhibitory fashion by dopamine. Drugs that interfere with dopamine receptors, such as phenothiazines, metoclopramide, reserpine and methyldopa, can increase prolactin release.

Dopamine agonists, such as bromocriptine and its derivatives, lower prolactin levels and are used in the treatment of hyperprolactinaemia.

THYROTROPIN

Circulating levels

The half-life of thyrotropin (TSH) is 50–60 minutes. Circulating TSH levels are readily measurable and used in the diagnosis of hypothyroidism and hyperthyroidism but are less use in diagnosing pituitary disorders. There is an early morning surge in TSH levels.

Effects

TSH, like LH, FSH and human chorionic gonadotrophin (HCG) are glycoproteins with an alpha and beta subunit. The alpha unit in all four hormones is identical. The beta subunit of TSH stimulates T4 and T3 release, and iodine uptake in the thyroid gland.

Control of secretion

TRH stimulates the release of the TSH and somatostatin inhibits it. T3 and T4 are also significant inhibitors of TSH release. They act at the pituitary level by reducing the amount of TSH that has released in response to TRH. Dopamine also inhibits TSH secretion. Bromocriptine will therefore decrease the TSH secretion and has been used to treat encountered TSH secreting pituitary adenomas that are uncommon.

GONADOTROPINS, LH AND FSH

Circulating levels

Levels of both hormones are low before the onset of puberty. In girls, the hormones are secreted cyclically at the onset of puberty and in boys there is a nocturnal rise in the secretion of LH at puberty.

In women, LH steadily increases and then peaks in the middle of the menstrual cycle stimulating ovulation. FSH is high early in the cycle, then steadily declines until mid-cycle when it surges. Both FSH and LH decrease in the second half of the cycle.

Both FSH and LH levels are high in postmenopausal women. In men, levels mirror those of the follicular phase in adult women.

Effects

These glycoprotein hormones differ only in their beta subunits and are secreted by the same cell. They regulate the noble function by stimulating sex steroid production and gametogenesis by the ovary and testis.

In women, LH stimulates oestrogen and progesterone production, stimulates ovulation and stimulates the corpus luteum to produce progesterone in the second half of the cycle. FSH controls the development of the ovarian follicle.

In men, FSH stimulates the Sertoli cells in their role in spermatogenesis and LH stimulates the Leydig to produce testosterone.

Control of secretion

GnRH stimulates the release of LH and FSH. It is released episodically and this pattern of release is necessary for controlling the onset of puberty and ovulation. In women, the circulating sex hormones influence GnRH secretion by both negative and positive feedback mechanisms at different parts of the menstrual cycle. Switching from negative to positive feedback results in the surges of FSH and LH seen in midcycle. In men, androgens stimulate the production of inhibin by the Sertoli cells and this hormone in turn inhibits GnRH secretion.

KEY POINTS

- A normal pituitary is approximately $8 \times 12 \times 4$ mm in size, weighing up to 500 mg.
- The lateral relation to the internal carotid artery and the rest of the contents of the cavernous sinus is variable.
- The sella turcica does not normally contain CSF.
- The anterior lobe hormones are ACTH; and growth hormones are TSH, LH, FSH and prolactin.
- The posterior lobe hormones are oxytocin and ADH.

PITUITARY ANATOMY AS IT RELATES TO IMAGING

High quality imaging of the pituitary and adjacent structures is essential in the management of pituitary adenomas. The development of magnetic resonance imaging (MRI) has been the greatest advance in this field in recent decades. Computed tomography (CT) scanning has a role, particularly for bone detail. On occasions conventional digital subtraction angiography (DSA) may be of use. These techniques have rendered more invasive and less effective imaging methods, such as air and contrast encephalography, redundant.

The detail of pituitary anatomy is described in Chapter 24, The pituitary gland: anatomy and physiology. In brief, the pituitary fossa lies in the posterior superior corner of the sphenoid sinuses. Its boundaries are as follows.

- **Anterior and inferior** – in well-aerated sphenoid sinuses, the bony walls of the sinuses form the anterior wall and the floor of the pituitary fossa. If the body of the sphenoid bone is poorly aerated, the

fossa is a recess in the posterior superior part of the body of the sphenoid bone itself.

- **Posterior** – the superior extension of the clivus, the dorsum sellae, forms the posterior wall of the fossa.

Together, these structures form a bony saddle in the skull floor, the sella turcica or Turk's saddle, in which the gland sits.

- **Lateral** – the cavernous sinuses are the soft tissue structures which form the lateral aspects of the pituitary fossa. They are venous lakes, which have dura mater and vein wall on their medial aspects separating them from the pituitary gland. Blood flows into them from the ophthalmic veins and pterygoid plexuses and out of them into the superior and inferior petrosal sinuses. They communicate across the midline by means of intercavernous connecting veins, whose size and position are extremely variable. They contain a range of important structures – the internal carotid arteries, and the oculomotor (III), trochlear (IV), abducent (VI), ophthalmic (V¹) and maxillary (V²) nerves.

- **Superior** – a thin structure called the diaphragma sellae forms the roof of the pituitary fossa. It is formed from the thin inner layer of the dura and the pia-arachnoid. This is perforated by the pituitary stalk and may actually be deficient at this point. Immediately above this is the suprasellar cistern, a space filled with cerebrospinal fluid (CSF).

THE USE OF IMAGING IN PITUITARY DISEASE

Imaging is used to identify the following.

- **Normality (Figure 25.1).** Imaging gives details of the size, shape, signal intensity (MRI) and signal density (CT) of the pituitary gland and adjacent structures.
- **Intrinsic abnormality (Figure 25.2).** MRI is the best technique to identify an intrinsic abnormality in a normal sized pituitary gland (tumour <10 mm in diameter – a microadenoma). However, in a patient with clinical features of a functioning adenoma, the presence of a localized abnormality within the pituitary can be misleading because:
 - there is a 10 percent incidence of asymptomatic pituitary adenomas in the general population and 10 percent of these are multiple;^{1,2} [***/**]
 - small functioning adenomas may not be visible on imaging – 25 percent in Cushing's disease;³ [***]
 - in Cushing's disease, there may be hyperplasia rather than an adenoma.⁴ [**]
- **Extrinsic abnormality (Figure 25.3).** If a tumour extends out of the fossa (tumour >10 mm diameter – a macroadenoma) imaging provides information on invasion or displacement of adjacent structures.
 - Superior extension (Figures 25.3 and 25.4). Pituitary adenomas most often extend superiorly into the suprasellar cistern where they may cause

symptoms by compression. Visual disturbance is the classical presentation, with superior temporal quadrantanopia as the presenting symptom due to compression of the inferomedial fibres in the optic nerves. The shape of the superior extension is

images (T2WI), in the axial, coronal and sagittal planes. Fat suppressed T1WI with contrast and dynamic contrast imaging and magnetic resonance angiography (MRA) are useful additional techniques.

- T1WI without contrast (**Figures 25.1** and **25.2**).
 - Soft tissue detail within the gland.
 - The appearance of normal anterior pituitary is uniform and in normal adults the adenohypophysis is isointense to cerebral white matter on standard T1WI. The adenohypophysis makes up approximately 70–80 percent of the total gland volume. The neurohypophysis can appear hyperintense on T1WI. This is due to the effect of stored neurosecretory phospholipid granules on T1WI. This hyperintense region is seen in up to 90 percent of children but is a less consistent finding in adults. In adults, the gland ranges from 8–10 mm in height in the sagittal plane, but may exceed 12 mm in height in the postpartum period. The upper contour of the gland is normally flat or concave but it may have a convex upper border in menstruating or lactating females and during puberty.
 - Asymptomatic non-neoplastic cysts, found in approximately 20 percent of autopsy specimens, may be hypointense, isointense or hyperintense, depending on their content. If a cyst has a high cholesterol, fat or protein content, it will be hyperintense on T1WI.
 - Microadenomas may be either hypointense or isointense (**Figure 25.2**). They may be homogeneous or have areas of cystic change. Haemorrhage into an adenoma can cause sudden visual deterioration and the T1WI may help to confirm this with an area of hyperintensity within the adenoma (**Figure 25.4**).
 - Adjacent structures.
 - T1WI also shows fat within the clivus and body of the sphenoid as high intensity and demonstrates cortical bone as low intensity (**Figure 25.4**).
 - The pituitary stalk is well seen in the CSF in the suprasellar cistern (**Figures 25.1** and **25.2**). The infundibulum tapers from the floor of the third ventricle to the pituitary gland. The diameter of the stalk normally does not exceed that of the basilar artery or 3 mm in diameter. It enhances after the administration of intravenous contrast, because it lacks a blood–brain barrier. Stalk deviation is best seen on coronal views and although it usually has a midline position it may deviate slightly from the midline.

important, because a concentric tumour will be more easily removed from below than a so-called ‘cottage loaf’ tumour, where there is a waist in the tumour at the level of the diaphragma sellae (see Chapter 258, Pituitary tumours: medical and surgical management).

- Lateral extension into the cavernous sinus is usually asymptomatic. If there is evidence of an oculomotor palsy, it is important to consider alternative pathology such as an invasive tumour or an aneurysm (**Figure 25.3**).
- Inferior extension into the sphenoid sinus. Once again, this is usually asymptomatic, but if a connection develops through the pituitary fossa between the CSF spaces and the nose, the patient can present with either a CSF rhinorrhoea or meningitis. This can occur if infarction or medical treatment of an extensive prolactinoma leads to marked tumour shrinkage of a locally invasive tumour. CT scanning is useful in this situation because it will define the extent of any bone defect.
- Features on imaging which suggest alternative pathology. There are a range of other conditions which can arise in this area and mimic nonfunctioning pituitary adenomas (see Chapter 258, Pituitary tumours: medical and surgical management).

MRI

MRI should include thin section T1-weighted images (T1WI) with and without contrast and T2-weighted

- The optic chiasm is well seen, although it is often difficult to define the optic nerves at the orbital apex on more anterior coronal cuts.
- The cavernous sinuses and the nerves within them are isointense. On coronal views, a clear line can often be seen between the anterior pituitary and the cavernous sinus. Invasion of the cavernous sinus by an adenoma may be clearly visible.
- The internal carotid arteries show well as flow voids.
- The air within the sphenoid sinuses and the cortical bone margins will appear black while the mucosa of the sphenoid sinus is easily seen to indicate the anatomy of the interior of the sinus. Extensive soft tissue encroaching from the pituitary into the sphenoid sinus indicates inferior extension of the tumour. Bone detail is best seen on CT (see below under CT scanning). Mucosal thickening or fluid levels seen within the sphenoids or other sinuses (on MRI or CT) raises the possibility of sinusitis.
- T1WI with contrast. The use of intravenous gadolinium as contrast is part of the routine imaging technique for investigating the pituitary.
 - Soft tissue detail within the gland.
 - Normal anterior pituitary enhances uniformly with contrast as it has no blood–brain barrier.
 - Cystic areas will have an impaired circulation, and will retain the intensity they had on the noncontrast image.
 - Microadenomas normally enhance less rapidly than normal pituitary tissue and hence appear hypointense on immediate contrast studies facilitating the diagnosis. They may appear hyperintense on delayed scans.
 - Macroadenomas may enhance to a variable degree and appear more heterogeneous than without contrast.
 - The cavernous sinuses will enhance with contrast. Depending on the imaging characteristics of any tissue extending into them, this can add information on the extent of a pituitary lesion. Other structures do not change significantly with contrast.
- T2WI is useful because of the high signal of CSF. This allows a clear definition of the upper surface of a small gland or a tumour extending out of the fossa into the suprasellar cistern. T2WI is also very useful to define an empty sella or an arachnoid cyst. The signal characteristics follow CSF on fluid attenuated inversion recovery (FLAIR) and diffusion weighted images (DWI).

CT scanning

This form of imaging can be used to enhance the information obtained from MRI. It is widely used in sinus surgery because of the precise information it gives with good demonstration of the air, soft tissue and bone details within the sinuses. Images can be acquired in the axial or coronal planes, and reformatted into any plane required. Good reformatting requires thin slice CT with contiguous images and the newer spiral/helical scans make this feasible. The use of CT scans does result in exposure of patients to moderate doses of radiation. It is indicated in pituitary tumours for the following reasons:

- to define bone detail in the sphenoid sinuses and the nasal anatomy;
- to demonstrate bone destruction of the pituitary fossa. This can be of the anterior wall, the floor or the dorsum sellae;
- to define the extent and severity of sinus infection;
- to assist in the diagnosis of other lesions such as meningioma or craniopharyngioma which may be partially calcified as calcification is best seen on CT.

Digital subtraction angiography

Digital subtraction angiography can be used if there are reasons to suspect a vascular lesion, such as an aneurysm or an arterio-venous malformation, although MRA may be used instead. In a pituitary lesion with an associated oculomotor palsy, an aneurysm should be part of the differential diagnosis because pituitary adenomas very seldom cause diplopia.

IMAGING OF THE PITUITARY AFTER SURGERY

Macroadenomas

Serial postoperative MR scanning is particularly valuable in large tumours. The 'base line' postoperative scan should be timed to allow the early effects of surgery, such as oedema and organization of tissue, to resolve. Subsequent scans then allow accurate monitoring of any change in the volume of residual tissue within the pituitary fossa and can be used to detect recurrence.

Microadenomas

Where the surgeon has performed an adenectomy or partial hypophysectomy for a microadenoma, interpretation is more difficult, because residual tissue within the fossa may be either the remaining normal tissue, or material which the surgeon inserted at the time of surgery, or recurrent adenoma. Serial scans can demonstrate growth of persistent tissue, which may indicate recurrent adenoma. In functioning adenomas, endocrine

assessment is probably a more reliable indication of cure, persistence or recurrence of disease.

The future of imaging

Recent advances in imaging technology will considerably improve the assessment of the sella and the parasellar pathologies. These include:

- an increase in magnetic strength of MR scanners with research scanners available at 9.4T with the potential for MR imaging to display very fine anatomic detail within CNS;
- open bore MR scanners which can allow real time image guided surgery;⁵ [*]
- image fusion for stereotactic surgery and radiotherapy planning;
- MR spectroscopy for correct diagnosis of lesions including post-radiotherapy necrosis;
- multislice CT scanners for quick scans which will prove excellent for noninvasive CT angiography;
- the development of positron emission tomography (PET) of pituitary tumours.

PITUITARY PHYSIOLOGY AS IT RELATES TO TESTS FOR NORMAL FUNCTION

The pituitary gland consists of an anterior part, the adenohypophysis, and a posterior part, the neurohypophysis, attached to the hypothalamus by the pituitary stalk. Both adenohypophysis and neurohypophysis are physically attached and physiologically intimately related to the hypothalamus, which lies immediately above the pituitary in the lateral walls of the third ventricle (see also Chapter 24, The pituitary gland: anatomy and physiology).⁶

The arterial blood supply of the whole gland is from the superior and inferior hypophyseal arteries, both of which are branches of the internal carotid artery. The superior hypophyseal arteries supply a plexus which is closely associated with the median eminence of the hypothalamus and the axons of the hypophysiotropic neurones within the hypothalamus. These vessels then form a pituitary portal circulation, which runs down the pituitary stalk into sinusoids in the anterior pituitary. The venous drainage of the gland is into the cavernous sinuses. These are venous lakes, which contain the last part of the internal carotid arteries, and the IIIrd, IVth, Vth and VIth cranial nerves. They are connected across the midline by a variable array of intercavernous connecting veins and they drain into the superior and inferior petrosal sinuses. The venous connections are of importance when considering inferior petrosal sinus sampling as a method of locating secreting adenomas.

The function of the hypothalamus and pituitary is highly complex and the pituitary is often described as the conductor of the endocrine orchestra. Neural and hormonal factors act on the hypothalamus to control the secretion from the pituitary. The hormones released from the pituitary either act on target organs (thyroid, adrenals and gonads), which then secrete the active hormones, or they act directly on target cells (prolactin, growth hormone/IGF1, vasopressin).

Hypothalamus

The hypothalamus exerts control over both the anterior and posterior pituitary. The control of the anterior part is via the portal circulation, and the hypothalamic axons extend directly into the posterior part.

In the case of the anterior gland, the hypophysiotropic cells within the hypothalamus are regulated by neural stimuli and feedback from the circulating levels of active hormones, whether secreted by the adenohypophysis itself (e.g. GH) or a target organ (e.g. thyroxine). Neurohormones are synthesized by the hypophysiotropic neurones, transported down their axons and released into the pituitary portal circulation, which carries them to target cells in the anterior pituitary. There is also a lesser direct feedback effect of circulating active hormones on the anterior pituitary cells themselves.

The neurohormones can have either a stimulatory or inhibitory effect on the cells of the anterior pituitary. The identified stimulatory neurohormones are gonadotrophin releasing hormone (GnRH), thyrotrophin releasing hormone (TRH), corticotrophin releasing factor (CRF) and growth hormone releasing hormone (GHRH). Examples of inhibitory neurohormones are somatostatin, inhibiting the release of growth hormone, and prolactin release inhibiting factor (PIF) hormone. Dopamine is either PIF or at least one PIF. When these neurohormones reach the target cells in the adenohypophysis they stimulate or inhibit the release of the specific hormone in question.

Adenohypophysis

The adenohypophysis is made up of three parts, the pars anterior which is 80 percent of the gland, the pars intermedia, which is small in adults but well developed in the foetus, and the pars tuberalis which is an upward extension of the anterior part wrapped around the lower end of the pituitary stalk.

The adenohypophysis secretes thyroid stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH), growth hormone (GH), prolactin (PRL) and two gonadotrophins, follicle stimulating hormone (FSH) and luteinizing hormone (LH).

Hormone secretion by the adenohypophysis is subject to marked cyclical rhythms. The cycle of secretion can vary widely with particular hormones. Seasonal rhythms are well recognized in the breeding cycles of many animals, but are probably unimportant in humans. In women, gonadotrophin secretion has a 28-day cycle which is critical for ovulation and implantation. The circadian rhythmic nature of ACTH release is well recognized. Normal growth hormone secretion has a diurnal rhythm and is pulsatile, with more pulses secreted during sleep.

Fluctuations in hormone secretion are important when assessing the level of a particular hormone for two reasons. First, the loss of the diurnal rhythm may be an important indicator of disease, as in Cushing's disease. Second, if the hormone has a short half-life, an isolated measurement of the hormone level can be very misleading if the rhythmic or pulsatile nature of its secretion is not taken into account. This is particularly true of growth hormone assays.

Neurohypophysis

The neurohypophysis is in continuity with the supraoptic and paraventricular neurones in the hypothalamus. Axons from these cells run through the stalk to the posterior pituitary. These cells synthesize and contain granules which pass down the axons. The granules are stored in the distal ends of the axons in the posterior pituitary and release oxytocin and vasopressin (ADH or antidiuretic hormone) into the systemic circulation when stimulated to do so.

Vasopressin has a direct effect on the distal convoluted tubules and medullary collecting ducts of the kidney, which it stimulates to reabsorb water. It also has a direct vasoconstrictive effect on vascular smooth muscle. Diabetes insipidus arises when vasopressin secretion is deficient and can be seen following pituitary surgery. However, this is not the only cause of a postoperative diuresis in hypophysectomy, and the syndrome of inappropriate antidiuretic hormone (SIADH) can arise in the postoperative period. It is essential to confirm that a diuresis is due to diabetes insipidus, by confirming that the plasma sodium levels are normal in the presence of a high output of dilute urine, before treating it with a vasopressin analogue such as DDAVP. Treating a diuresis with DDAVP in the presence of SIADH may cause a serious fall in sodium levels, which may cause severe complications.

Oxytocin secretion causes milk ejection during lactation and uterine contraction during labour. Oxytocin release is stimulated by mechanical stimulation of the nipple during lactation. During labour, stimulation of receptors in the pelvic wall leads to stimulation of the hypothalamic neurones which release oxytocin.

THE BIOCHEMICAL INVESTIGATION OF FUNCTIONING AND NONFUNCTIONING ADENOMAS AND LESIONS ARISING ADJACENT TO THE PITUITARY

Anterior pituitary

PROLACTIN AND PROLACTINOMA

Human prolactin is a protein consisting of 199 amino acids. It has similarities with growth hormone. Its predominant and most active form is a monomer, but it also circulates as a dimer and a polymer. The serum prolactin level is a reliable measure of this hormone. It is used to diagnose prolactinoma and to monitor the effect of treatment. The normal circulating level will depend on the laboratory, but the normal range in our centre is 60–620 mU/L. Circulating levels are higher in women than in men.

Prolactin regulation is via neural and feedback pathways to the hypothalamus and anterior pituitary. Inhibitory factors – PIF – and releasing factors are involved in the control of prolactin release. The main PIF is dopamine. Twelve to twenty-eight percent of cells in the normal anterior lobe produce prolactin. The control of secretion is complex and a wide range of factors and conditions influence prolactin secretion.

The main site of action of prolactin is the mammary gland where it acts to prepare for milk production and maintain it. Physiological and pathological hyperprolactinaemia also suppresses the hypothalamo-pituitary axis and suppresses the release of GnRH and therefore gonadotrophins. These effects can cause galactorrhoea and amenorrhoea in women. In men there may be little effect but low gonadotrophin levels may reduce the secretion of testosterone, causing loss of libido.

Physiologically high levels of prolactin are to be expected during pregnancy and lactation. Pathological causes of high prolactin levels are due to autonomous secretion of prolactin by the pituitary as in a prolactinoma, or because of loss of PIF from the hypothalamus. In prolactinomas the prolactin levels can be very high – over 10,000 mU/L. In nonfunctioning adenomas there may be a moderate rise in prolactin levels, up to approximately 2000 mU/L, probably because of a loss of PIF due to the effect of the adenoma and stalk compression. In other functioning adenomas, such as GH secreting adenomas, prolactin may be elevated because this hormone can be produced in excess along with growth hormone.

It is important to remember that when a pituitary macroadenoma is identified on imaging, a modest elevation of serum prolactin (up to 2000 mU/L) can be anticipated in a nonfunctioning tumour. Conversely, prolactinomas may cause little in the way of symptoms, particularly in men, and no pituitary macroadenoma should be assumed to be nonfunctioning unless the serum prolactin is less than 2000 mU/L.

Dopamine agonists, such as bromocriptine and cabergoline, are the first line treatment for prolactinomas. Serum prolactin levels can be used to monitor their effect, but imaging should also be used, particularly in the presence of a macroadenoma (>10 mm in diameter on imaging). On this treatment the levels of circulating prolactin should fall and the tumour shrink. However, a biochemical response is not invariable and if it occurs it does not guarantee tumour shrinkage. The indications for surgery and its results are discussed in Chapter 258, Pituitary tumours: medical and surgical management. Serum prolactin levels are also used to monitor the results of other forms of treatment, namely surgery or radiotherapy.

GROWTH HORMONE AND ACROMEGALY

Seventy to eighty percent of GH is a single chain 191 amino acid protein. Other forms of the hormone are also secreted. Approximately half the cells in the anterior pituitary secrete GH. GH acts either directly on cells when it binds to GH receptors, or indirectly when it triggers the production of insulin-like growth factors (IGFs) which are mainly synthesized in the liver. IGF1 is the most important of these. The serum concentration of IGF1 is a good indicator of the mean concentration of GH over time. Concentrations of GH and IGF1 can be measured in serum, but because normal secretion of GH is pulsatile and the hormone has a short half-life in circulation and IGF1 has a long half-life, IGF1 concentration is a very useful indicator of the mean GH output.

The regulation of GH output is highly complex, but it is both neural and by the feedback mechanism. Secretion is controlled by at least two antagonistic peptides from the hypothalamus, GHRH, which stimulates secretion and somatostatin, which inhibits it.

Because GH secretion is pulsatile, the quantity secreted can be varied by the frequency or the amplitude of the pulses. When considering the diurnal rhythm, output is highest during slow wave sleep. Over a lifetime, output is highest during adolescence and decreases with age. A random GH is normally less than 5.5 mU/L.

GH is anabolic and stimulates protein synthesis. It is essential for normal growth and protein metabolism. It also induces lipolysis. It is secreted during hypoglycaemia, releasing energy from body stores. Conversely, hyperglycaemia suppresses GH output. GH antagonises insulin and induces hyperglycaemia. This is why acromegaly may induce the onset of diabetes mellitus or make it worse.

Because of the way in which GH is secreted in normal individuals, it may be high at times and undetectable at others, making a random estimation of serum GH levels unreliable in the assessment of pituitary function. In order to confirm that GH levels are elevated, it is important to measure GH during an oral glucose tolerance test (OGTT). A high blood sugar should

suppress GH output, but it will not do so if an adenoma is secreting GH autonomously. During such a test, as long as the blood glucose level rises above 6 mmol/L, GH should suppress to less than 2 mU/L. It is important to measure the blood glucose levels during the test.

Levels of GH during an OGTT and IGF1 are reliable in the diagnosis of acromegaly and to monitor the effects of all forms of treatment.

The diagnosis of GH deficiency in childhood is critical as treatment has to be instituted early for the patient to achieve normal growth. Post-surgical GH deficiency in adults is an area of increasing interest. Patients who have received treatment to the pituitary may become GH deficient. Symptoms are often nonspecific, diagnosis may be difficult but there is increasing evidence that some patients derive significant benefit from receiving replacement GH.

ACTH, CUSHING'S DISEASE, CUSHING'S SYNDROME AND NELSON'S SYNDROME

ACTH is a 39 amino acid peptide. It is derived from a large precursor protein which is found in the corticotrophic cells of the anterior and intermediate lobes of the pituitary, in some neuronal cell groups, in peripheral chromaffin cells and some immune cells. In the anterior pituitary, 6–10 percent of cells are corticotrophs.

ACTH has a short circulating half-life and it is more usual to assay plasma cortisol levels and 24 hour urinary free cortisol production to screen patients for Cushing's syndrome. Both these can be reliably measured. In normal subjects, plasma cortisol levels are highest in the morning and lowest at night. This diurnal rhythm can be measured. In Cushing's syndrome, this rhythm is absent and plasma cortisol and urinary free cortisol levels are elevated.

Normal ACTH output is regulated by CRF and vasopressin. These two potentiate each other, but CRF output is suppressed by high circulating levels of glucocorticoids, whereas vasopressin is not. ACTH acts mainly on the adrenal cortex which secretes glucocorticoids, mineralocorticoids and androgens.⁷

Diagnosing Cushing's syndrome

- Circulating glucocorticoid levels and 24 hour urinary free cortisol can be measured by routine laboratory assays. Normal plasma cortisol levels are subject to large diurnal variation and the precise levels will depend on the laboratory used. In this institution the normal levels are 180–550 nmol/L at 9.00 a.m. and <130 nmol/L at 12 midnight. Loss of the diurnal rhythm is a feature of Cushing's syndrome. Measurement of 24 hour urinary free cortisol output is also a useful measure of glucocorticoid production and provides a screening test for Cushing's syndrome.

- The low-dose dexamethasone test (see Differentiating Cushing's disease from Cushing's syndrome) is also of value to diagnose Cushing's syndrome. In this test, plasma cortisol is effectively suppressed in normals, but not in those with autonomous ACTH secretion.
- Insulin tolerance test. Depressed patients may show some of the clinical features of Cushing's syndrome and lose the circadian rhythm of cortisol output. Insulin-induced hypoglycaemia can be used to distinguish depressed patients from those with Cushing's syndrome because it will induce a rise in ACTH in the former but not the latter. Adequate hypoglycaemia must be induced and in Cushing's syndrome, this may require quite large doses of insulin.

Differentiating Cushing's disease from Cushing's syndrome

In suspected Cushing's syndrome, once raised plasma cortisol and urinary free cortisol levels have been detected, it is important to establish the cause. This could be due to excess production from the adrenal glands themselves, as in an adrenal adenoma or carcinoma, or due to excessive stimulation of the adrenal cortex by overproduction of ACTH, secreted from the pituitary or from an ectopic source. The commonest cause of Cushing's syndrome is excess ACTH from the pituitary (70 percent) – Cushing's disease – but this must be defined if treatment is to be appropriate and effective. A number of tests exist to achieve this.

- If the source of glucocorticoids is adrenal, the plasma ACTH level is low.
- Hypokalaemic alkalosis is a feature of Cushing's syndrome due to ectopic ACTH, but not of Cushing's disease.
- The dexamethasone suppression test. The high-dose part of this test is used to differentiate between a pituitary source and an ectopic source of excess ACTH. There are several variations in the test, but they hinge on the fact that there is a differential sensitivity on the feedback mechanism with increasing doses of dexamethasone in the different causes of Cushing's syndrome. Dexamethasone is a powerful glucocorticoid, which acts centrally via the feedback mechanism to suppress ACTH output. At low dose (0.5 mg four times a day) it will suppress secretion of ACTH in normal subjects, but the effect is insufficient in those with autonomous ACTH

secretion. However, pituitary secretion of excess ACTH is not totally autonomous, and so high doses of dexamethasone (2 mg four times a day) will suppress ACTH output from the pituitary. Ectopic sources of ACTH are more autonomous and suppression does not occur on either low-or high-dose dexamethasone. There are a number of variations in this test, but the full test is run over four days, with the low dose being given for 48 hours, then the high dose being given for 48 hours. The plasma cortisol levels and the urinary free cortisol levels are measured during the test. Unfortunately, this test is not invariably accurate because 10–20 percent of ACTH secreting pituitary adenomas do not suppress on high dose whereas 50 percent of ACTH secreting bronchial carcinoid tumours show some suppression on high dose. It is therefore important to have additional evidence of a pituitary adenoma before concluding that the cause of Cushing's syndrome is a pituitary adenoma as opposed to an ectopic source of ACTH. The test is summarized in Table 25.1.

- CRF test. If CRF is administered, ACTH levels will rise in normals and this response is exaggerated in Cushing's disease, but it is typically absent if the source of ACTH is ectopic. In most cases, CRF has more effect on ACTH levels if the source is the pituitary rather than if it is an ectopic source, but once again this test is not foolproof. Up to 10 percent of pituitary adenomas do not respond to infused CRF as would be expected and a few ectopic ACTH producing tumours do respond by secreting more ACTH.
- Metyrapone test. This drug blocks glucocorticoid metabolism and if given to normal people it will cause a rise in ACTH. This response is usually exaggerated in Cushing's disease, but not if the source of ACTH is ectopic.
- Inferior petrosal sinus sampling (IPSS). This test is used as a further means of defining the source of excess ACTH. It also holds out the prospect of localizing the source of ACTH within the pituitary itself. Because some adenomas are so small that they cannot be demonstrated on scanning (see below), this is an attractive prospect, but localization is not as accurate as might be anticipated. This is an invasive technique, requiring selective cannulation of both inferior petrosal sinuses under radiographic control via the femoral vein. With the catheters in place, samples

Table 25.1 The dexamethasone suppression test.

	Normal	Pituitary Cushing's	Ectopic Cushing's
Low-dose dexamethasone	Suppression of plasma cortisol and UFC	No effect	No effect
High-dose dexamethasone	Suppression of plasma cortisol and UFC	Suppression of plasma cortisol and UFC	No effect

can be taken for hormonal assay. After baseline samples have been taken to assay the pituitary hormone levels from each side, CRF is administered intravenously and further samples are taken to measure the effect on pituitary hormone output. IPSS is most useful to confirm that the source of ACTH is the pituitary. It is therefore used when Cushing's disease is suspected but imaging does not confirm the presence of an adenoma and there is doubt as to whether the source of excess ACTH is the pituitary or ectopic. High levels of ACTH in blood obtained from IPSS are strongly indicative of a pituitary source of ACTH. A differential between the levels of ACTH in the IPS and a peripheral sample is further evidence of a pituitary source. If this is combined with a CRF test, a rise in the ACTH levels can be demonstrated with CRF. This raises the sensitivity of the test to 95 percent.⁸ [***] Although there are large venous connections between the cavernous sinuses, the venous blood between the two may not mix very much.⁹ [**] If there is a marked difference in the ACTH levels between the two sides, without a similar asymmetry in the levels of the other pituitary hormones (prolactin, GH, FSH and LH), tumours can be localized by this technique. Unfortunately, venous drainage is variable and IPSS only assists localization in 50–70 percent of cases.^{8, 10} [***/**] In summary, this technique is quite invasive and is reserved for more difficult diagnostic cases. It is certainly useful to confirm high levels of ACTH output and so to confirm a pituitary source of Cushing's but, disappointingly, localization is less accurate.

Nelson's syndrome

This is a condition which arises when bilateral adrenalectomy is performed to relieve Cushing's disease and the pituitary lesion then expands more rapidly because of the loss of feedback from the high circulating steroid levels. The clinical features are those of an expanding pituitary mass with visual and ocular effects and hyperpigmentation due to the high circulating levels of ACTH.

Details of the biochemical tests used to diagnose and define Cushing's disease and syndrome are widely discussed in most textbooks of endocrinology. The conclusion is that biochemical testing does not yet provide 100 percent accuracy in distinguishing ACTH generated by a pituitary microadenoma from that produced by an ectopic tumour.

TSH AND TSHOMA

TSH secreting adenomas are rare, representing a very small percentage of functioning adenomas. Patients may present with features of hyperthyroidism but on investigation for this they are found to have normal or elevated TSH levels rather than the suppressed levels which would be anticipated in thyrotoxicosis of thyroid origin.

If a TSHoma is suspected, an MR scan of the pituitary gland should be undertaken. Tumours may be either micro- or macroadenomas. Treatment options include surgical excision, radiotherapy or medical treatment. TSHomas may respond well to somatostatin analogues. They can also be more aggressive than other pituitary adenomas and so long-term biochemical and imaging follow-up is appropriate. Radiotherapy is an option which should be considered if the disease is not cured by surgery.

OTHER FUNCTIONING ADENOMAS

Gonadotrophinomas seldom present as functioning tumours. Typically this diagnosis is made on immuno-histochemical analysis of a nonfunctioning adenoma following surgery. These tumours will therefore be discussed under nonfunctioning adenomas.

NONFUNCTIONING PITUITARY ADENOMAS

As the name indicates, these tumours do not present with any overt effect of excess hormone release. Their typical presentation is of a space occupying lesion spreading out of the pituitary fossa. In relation to pituitary function, there are key points that are essential in their correct management.

- Identification of associated hypopituitarism. Patients with these lesions may be partially or completely hypopituitary. The classic finding is progressive loss of pituitary hormone secretion with gonadotrophins (LH and FSH) affected first, then GH, TSH and ACTH, but variations do occur. In children, cessation of growth or delayed puberty are the most common presentations. Once clinically suspected, this can be confirmed by measuring plasma cortisol levels, urinary free cortisol, gonadotrophins, GH, testosterone, prolactin (may be elevated in nonfunctioning pituitary adenomas (NFAs), see above) and thyroid function. However the tumour is managed, it is essential to ensure that any hormone deficiencies are corrected for the patient's well-being and before surgery is undertaken.
- Identification of an asymptomatic functioning adenoma. It is particularly important to recognize a prolactinoma, because medical treatment may render surgery unnecessary.

There are a range of other pathologies which arise in and adjacent to the pituitary gland. These are described in Chapter 258, Pituitary tumours: medical and surgical management.

Posterior pituitary function

Diabetes insipidus is caused by lesions of the pituitary gland. The commonest causes are trauma and surgery (see below under Pituitary function in the postoperative period).

VISUAL FIELD ASSESSMENT

- If a patient with a pituitary tumour complains of any visual disturbance, this needs to be fully assessed preoperatively. An ophthalmologist's opinion and documentation of visual fields are important.
- In the presence of a macroadenoma with tumour abutting on the nerves or chiasm, even if there are no ocular symptoms, visual field assessment is essential pre- and postoperatively.
- If there is a microadenoma with no evidence of tumour reaching the nerves or chiasm on imaging and no ocular symptoms, this is unnecessary.

The typical visual field abnormality is a bitemporal superior quadrantanopia or hemianopia, but this will depend on the position of the optic chiasm in relation to the pituitary. The earliest detectable abnormality is loss of perception of a red target. In most cases, the visual field impairment is reversible if detected and treated early.

PITUITARY FUNCTION IN THE POSTOPERATIVE PERIOD

In functioning adenomas, successful surgery should correct the excess of hormone secreted by the adenoma. It may render the patient deficient in other pituitary hormones. It is unlikely to restore hormone levels which were deficient preoperatively.

Hormone assays are used to assess the results of treatment. In microadenomas a resolution of the hormonal excess and persistently normal or low levels of that hormone indicate a cure and are a more accurate method of assessing the results of treatment than imaging. It is essential to test for all the pituitary hormones because the patient may develop a deficiency of any of them. If the pituitary is irradiated, the onset of hypopituitarism may be gradual. Lifelong follow-up is important, as recurrence or hypopituitarism can occur years later.

Patients must have a formal endocrine assessment postoperatively. Our routine is to formally assess all patients fully at approximately one month. Until then, patients are put on physiological doses of hydrocortisone (15–20 mg of hydrocortisone in the morning and 5–10 mg in the afternoon) and should continue to take any other replacement therapy which they needed preoperatively. At one month they have the following:

- a short Synachthen test and only if the patient passes this does she or he stop hydrocortisone;
- in treated Cushing's disease, a plasma cortisol after taking no hydrocortisone for 24 hours;
- in all cases, the range of tests for anterior pituitary function;

- in functioning adenomas, the appropriate test to define whether a cure has been achieved:
 - in Cushing's, a plasma cortisol of less than 30 nmol/L would indicate a cure. Even if normal gland has been left at surgery, it often takes months for normal cells to recover function and so such low levels at one month do not necessarily indicate permanent low levels of ACTH. Results within the normal range (180–550 nmol/L at 9 a.m. and <130 nmol/L at midnight) may not indicate failure to cure, but are suspicious. Results above the normal range indicate failure. Similarly, urinary free cortisols should be low or normal at this time;
 - in acromegaly, the best assessment is serial measurement of GH through an oral glucose tolerance test and of IGF1. If a fasting growth hormone is below 5 mU/L, it suppresses to less than 2 mU/L with adequate hyperglycaemia and the IGF1 is within normal limits (13–37 nmol/L) the patient is probably cured;¹¹ [**]
 - in prolactinoma, the serum prolactin should return to normal (60–620 mU/L);
 - in TSHoma, thyroid function tests should reveal a low TSH. The patient may become hypothyroid but still have a low TSH;
- posterior pituitary function does not need formal assessment unless the patient has symptomatic diuresis. If this is the case, diabetes insipidus needs to be diagnosed by a water deprivation test and then treated with DDAVP.

In the early postoperative period, the results for Cushing's disease can be predicted usefully by measuring a plasma cortisol at 72 hours with the patient off all replacement glucocorticoids for 12 hours. A plasma cortisol of less than 30 nmol/L is highly predictive of a surgical cure. In acromegaly, an early measurement of GH is less reliable.

KEY POINTS

- MRI has value and limitations in the diagnosis of pituitary adenomas.
- CT scanning is important for checking bone detail in the sinuses and pituitary fossa.
- Preoperative biochemistry is important in avoiding unnecessary surgery in macroadenomas.
- A multidisciplinary approach with endocrinologists is essential to avoid incorrect diagnosis and optimize management of pituitary tumours.

Best clinical practice

- ✓ Check serum prolactin levels preoperatively in pituitary macroadenomas.
- ✓ Prolactinomas respond well to dopamine agents.
- ✓ Inferior petrosal sinus sampling is essential when there is doubt about the origin of Cushing's syndrome.
- ✓ Long-term follow-up is essential to avoid missing late recurrence of pituitary adenomas.

Deficiencies in current knowledge and areas for future research

- Imaging is developing rapidly. As the new technologies outlined above become more widely available, it is to be hoped that uncertainties in adenoma location should be reduced. The ability to monitor surgical progress intraoperatively is most valuable. These innovations should improve surgical outcomes.
- The most difficult syndrome to accurately diagnose and cure is Cushing's. Improvements in the ability to define the precise source of ACTH will allow even more accuracy in identifying which patients should have pituitary surgery and which part of the gland should be removed to cure this otherwise lethal disease.

SEARCH STRATEGY AND EVIDENCE-BASE

Medline and Embase searches were performed using the key words: thyroid gland, anatomy, histopathology, microstructure, physiology, thyroid hormone and calcitonin. Extensive reference has been made to the extremely comprehensive eighth edition of Werner and Ingbar's classic textbook *The thyroid: a fundamental and clinical text*. This chapter summarizes and reviews the observational studies that relate to anatomy and physiology of the thyroid gland and are therefore levels 3 and 2 evidence.

INTRODUCTION

The aim of this chapter is to provide an overview of the key anatomical and physiological facts which are relevant to surgeons wishing to develop a practice in thyroid surgery and highlight some of the more recent developments of our understanding of thyroid physiology.

The thyroid gland is a bilobed structure situated in the lower anterior neck. It is a highly vascular, reddish-brown organ with two primary endocrine functions: secretion of thyroid hormones, namely thyroxine (T_4) and triiodothyronine (T_3), from follicular cells and calcitonin from parafollicular or C cells. The thyroid hormones ensure that the metabolic demands of the tissues of the body are met by stimulating oxygen consumption and regulating carbohydrate and lipid metabolism. They are also essential for normal growth and maturation. Calcitonin is released rapidly in response to elevated levels of circulating calcium ensuring levels do not fluctuate wildly and thereby helping prevent hypercalcaemia. The thyroid gland itself is not necessary for life but low levels of thyroid hormone (hypothyroidism) can cause severe mental and physical impairment and disability.¹

An excellent historical review of the key developments in our understanding of the thyroid gland anatomy and function can be found in Sawin.² More recent developments have focused on the function and controlling mechanisms at the molecular genetic level.^{3,4} **Table 26.1** provides a summary of the key developments.

ANATOMY OF THE THYROID GLAND

Embryology

In higher vertebrates, including humans, the thyroid develops from fusion of a median anlage with two lateral anlagen, which originate from two distinct regions of the endodermal pharynx.⁵ Colloid production starts at 13–14 weeks gestation followed almost immediately by the development of follicles.^{6,7} Thyroxine can be detected in foetal serum at 11–13 weeks.⁸

MEDIAN ANLAGE

The median anlage (**Figure 26.1**) develops from a midline thickening of the ventral surface of the primitive

Table 26.1 Historical summary.

Year	Contribution
BC	Goitres recognized by Chinese and Europeans living in Alps
c. 200 BC	Ancient Greeks called the thyroid swelling a bronchocele or tracheal outpouch
c. 1500	Leonardo da Vinci was most likely the first to describe the thyroid gland
1543	Vesalius described the thyroid as a 'laryngeal gland' for lubricating of the vocal cords
1619	Fabricius made the link between the thyroid gland and goitre
1656	Thomas Wharton coined the term 'thyroid' from the Greek meaning 'shield shaped' (referring to its proximity to the thyroid cartilage)
c. 1527/1562	Parcelsus and Platter recognized the clinical significance of goitre and cretinism
1820	Coindet gave potassium iodine to a Swiss patient with goitre and noticed a significant decrease in its size
1825	Parry described thyrotoxicosis without realizing it
1834	Graves described thyrotoxicosis in four patients with goitre and palpitations, one of whom also had exophthalmos, although this was thought to be of cardiac origin
1870s	Myxoedema first recognized but thought to be a neurological or skin disease
1876	Thyroid surgery for goitre introduced by Emil Kocher
1883	Felix Semon first made the link between myxoedema and hypothyroidism
1888	Cretinism, myxoedema and post-thyroidectomy all recognized as being due to one cause, i.e. a loss of thyroid function
1890s	Thyrotoxicosis thought to be due to either excess secretion of a substance or failure of inactivation of a toxin
1891	Murray cured myxoedematous patients with injected extracts of sheep's thyroid gland
1895	Baumann found iodine in the thyroid gland
1897	Tourneaux and Verdun describe the embryological development of the thyroid gland
1914	Edward Kendall isolated thyroxine
1926–7	Harington discovered structure of thyroxine and then synthesized it. However at that time it was too expensive for therapeutic use. Thyroid deficiency and goitre was treated with desiccated thyroid until the 1960s
1952	Pitt-Rivers and Gross in the UK discovered triiodothyronine almost simultaneously with Roche, Lissitsky and Michel in France
1970	Sterling demonstrated the conversion of T_4 to T_3 in normal human subjects

pharynx between the first and second branchial arches adjacent to the developing myocardium.^{9,10} A diverticulum forms from this thickening at approximately the 16th or 17th gestational day. This can be recognized as a small blind pit in the midline between the anterior two-thirds and posterior third of the tongue and is known as the **foramen caecum**. The diverticulum expands at its distal tip leading to the formation of a bilobed structure. This then migrates into the lower neck anterior to the hyoid bone, laryngeal cartilages and pharyngeal gut. It is pulled into position by the descent of the heart and reaches its final location, immediately anterior to the trachea, in the seventh gestational week. The lumen of the stalk is initially tubular but becomes filled with cords of cells during the seventh to tenth week of gestation but eventually fragments and disappears. Persistence of part of the stalk anywhere between the foramen caecum and thyroid isthmus can result in the development of a thyroglossal duct cyst.¹¹ When present, the cysts are most commonly found between the hyoid bone and isthmus.^{12,13} Alternatively, and more rarely, thyroid descent may become arrested anywhere along the tract resulting in a lingual thyroid¹⁴ or giving rise to ectopic thyroid tissue in the sublingual, high cervical and mediastinal regions or even within the cardiac endothelium.⁵

LATERAL ANLAGEN: ULTIMOBRANCHIAL BODIES

The two lateral anlagen (**Figure 26.1**), known as the ultimobranchial bodies, are thought to develop as caudal projections from the fourth or fifth pharyngeal pouches. They become separated from them by attenuation and rupture of the common pharyngobranchial duct. The ultimobranchial bodies fuse with the median thyroid anlage by the sixth week of development contributing approximately 10 percent of the mass of the thyroid gland.^{15,16} Rarely, the ultimobranchial bodies can fail to fuse resulting in a true 'lateral thyroid lobe'.

The ultimobranchial bodies also contribute the parafollicular calcitonin-producing cells (C cells). The exact origin of these cells in humans remains controversial although they are thought to be most likely of neural crest origin.⁵ Normally, the parafollicular cells migrate to become distributed throughout the gland although they often remain more numerous near the point of fusion between the two anlagen.^{7,17} It is therefore not surprising that medullary carcinomas develop in the central portions of the middle and upper thirds of the thyroid lobes.¹⁸ Lateral thyroid lobes, when present, are also often associated with a greater than normal amount of parafollicular tissue and an increased tendency to become neoplastic.¹⁹

Figure 26.1 Schematic representations of the early development and origin of the follicular and parafollicular (C cells) of the thyroid gland and chief cells of the parathyroid glands.

Macroscopic anatomy

The thyroid gland is the largest endocrine organ in the body weighing between 15 and 25 grams in adulthood and being slightly larger in women. It consists of two lobes joined together by an isthmus (**Figure 26.2**).

Each lobe is pear-shaped measuring approximately 5 cm in length, 3 cm in width and 1.5 cm in depth. Very rarely, one lobe of the thyroid gland fails to develop (more often on the left). The apex of each lobe is narrow and extends beneath the sternothyroid muscle up to its insertion on the oblique line of the thyroid cartilage. The more rounded lower pole extends down to the level of the fourth or fifth tracheal ring and lies lateral to the trachea and oesophagus and medial to the carotid sheath. The isthmus lies immediately caudal to the inferior border of the cricoid cartilage.

A third conical protrusion of varying size, known as the pyramidal lobe, can also be present in up to 50 percent of cases. It represents a distal remnant of the thyroglossal duct and can extend superiorly up to the level of the thyroid cartilage or hyoid bone.⁷ Its apex may be replaced by fibrous or fibromuscular tissue when it is then known as the 'levator of the thyroid gland'. Identifying and removing the pyramidal lobe should be part of a routine thyroid lobectomy to avoid leaving functioning thyroid tissue behind.

A lateral or posterior projection of the thyroid lobe, known as the tubercle of Zuckerkandl, can be identified in up to 60 percent of surgical dissections according to Gauger.²⁰ It is thought to represent the point of embryological fusion of the ultimobranchial body and median anlage. Its surgical importance is reported as being three-fold: (a) the recurrent laryngeal nerve most often runs medial to it; (b) the superior parathyroid gland is usually attached to its cranial aspect; (c) and when enlarged as part of the goitre it can be inadvertently left behind, particularly during a subtotal thyroidectomy.

Figure 26.2 Thyroid gland showing relationship to larynx and trachea. In up to 50 percent of cases, a pyramidal lobe ± a fibrous or fibromuscular band may arise from the isthmus and extend a variable distance up to the body of the hyoid.

The thyroid gland is invested in pretracheal fascia, which is part of the deep cervical fascia. Its uppermost attachment is limited by the attachment of the strap muscles (sternothyroid, sternohyoid and omohyoid) to the oblique line on the thyroid cartilage laterally and the hyoid bone more medially. As it passes inferiorly it splits to enclose the thyroid gland, allowing the surrounding

structures to slide over the gland. The fascia is not adherent to the thyroid gland except where there are penetrating vessels posteriorly between the isthmus and lower part of the cricoid cartilage down to the fourth tracheal rings. This fixation to the trachea causes the thyroid gland to move up and down on swallowing. The posterior condensation of fascia is known as the lateral ligament of the thyroid or the 'suspensory ligament of Berry'. It is usually penetrated by small blood vessels. During thyroid surgery it must be divided with care and by sharp dissection as the recurrent laryngeal nerve may lay lateral, medial or within the ligament just before it enters the larynx. A further posterior extension of the fascia passes behind the oesophagus allowing the anterior neck structures to glide over the prevertebral fascia and underlying prevertebral muscles on swallowing and neck movements. Laterally, the pretracheal fascia blends with the carotid sheath while inferiorly it passes behind the brachiocephalic veins to blend with the adventitia of the arch of the aorta.

ARTERIAL SUPPLY

The main blood supply of the thyroid gland is from the paired superior and inferior thyroid arteries. In up to 12 percent of cases a thyroidea ima artery may also be present ascending in front of the trachea to end at the isthmus. It most commonly arises from the brachiocephalic artery but it can also originate from the aorta, the right common carotid, subclavian or internal thoracic arteries.

The superior thyroid artery passes antero-inferiorly from its origin on the anterior surface of the external carotid artery just below the level of the greater cornu of the hyoid bone. It lies on the inferior constrictor muscle to reach the superior pole of the thyroid gland where it divides into an anterior and posterior branch. The anterior branch follows the medial margin of the superior lobe to the isthmus to anastomose with its opposite number. Several descending arteries pass from this arcade over the anterior surface of the gland to anastomose with branches from the inferior thyroid artery. The posterior branch descends on the posterior surface of the gland and in 45 percent of cases it joins with the ascending branch of the inferior thyroid artery.²¹ Additional lateral branches may also be present (Figure 26.3).

The inferior thyroid artery usually arises from the thyrocervical trunk, a branch of the first part of the subclavian artery, although in approximately 15 percent of cases it may come directly off the subclavian artery. It ascends in front of the medial border of the scalenus anterior muscle turning medially in front of the vertebral arteries and then behind the carotid sheath and the sympathetic trunk. It then descends on the anterior surface of the longus colli muscle to the lower border of the thyroid. Before reaching the gland it divides into ascending and descending branches on the posterior border of the gland. The superior parathyroid usually

Figure 26.3 Schematic representation showing a common relationship between the superior and inferior thyroid arteries, parathyroid glands and recurrent laryngeal nerve. On the right side the nerve passes behind, between or occasionally in front of the inferior thyroid artery while on the left side it most commonly passes behind the artery.

receives a terminal blood supply, either from its anastomosis with the posterior branch of the superior thyroid or directly from the superior thyroid artery.²¹ The inferior parathyroid is also supplied by a terminal branch: this arises from the descending branch as it passes towards the inferior pole to anastomose with its opposite number.

In addition to supplying the thyroid gland, the inferior thyroid artery gives off branches to the trachea, oesophagus and lower part of the pharynx. The inferior laryngeal artery, a branch of the inferior thyroid artery, ascends with the recurrent laryngeal nerve on the trachea to enter the larynx deep to the inferior constrictor muscle.²² It is often accompanied by a small plexus of veins in the region of the ligament of Berry, especially where the nerve enters the larynx. The vessels invariably have to be divided during thyroid dissection and great care is required with haemostasis to avoid damage to the nerve.

VENOUS DRAINAGE

The veins in the substance of the thyroid and on its surface form a venous plexus and drain via three main groups, namely the superior, middle and inferior thyroid

veins. The superior thyroid veins accompany the corresponding artery and drain into the internal jugular or occasionally the facial vein. The middle thyroid veins arise from the lateral surface of the gland near the junction of the middle and lower thirds of the thyroid gland. They may be double or absent. They receive blood from the inferior and antero-lateral part of the gland as well as the larynx and trachea. They most commonly cross the common carotid artery to drain into the internal jugular vein.

Multiple inferior thyroid veins form a plexus on the anterior surface of the trachea on leaving the gland. These usually drain into right and left inferior veins, which in turn drain into their respective brachiocephalic vein in the superior mediastinum. Occasionally these paired inferior veins form a common trunk and drain into the superior vena cava or left brachiocephalic vein.²³

LYMPHATIC DRAINAGE

The thyroid gland contains a rich network of lymphatics, which drain into several main groups of nodes in the anterior and lateral aspects of the lower neck (Figure 26.4). The lateral aspects of the gland drain into the middle and lower jugular nodes (levels III and IV) and those of the posterior triangle (level V). The more medial aspects of the gland also drain into the nodes of the anterior compartment of the neck (level VI), which in turn can drain into those of the upper anterior mediastinum (level VII). From a clinical perspective, levels I and II are rarely involved in metastatic thyroid cancer disease.

NERVES

Although the recurrent laryngeal and external branch of the superior laryngeal nerves do not actually supply the thyroid gland, their close proximity to the gland render them an extremely important consideration during the assessment of thyroid conditions and in thyroid and parathyroid surgery. The recurrent laryngeal nerves (Figure 26.5) are branches of the vagus nerve, which supply all the intrinsic muscles of the larynx except the cricothyroid muscle. They also supply sensory fibres to the mucous membrane below the level of the vocal folds and carry afferent fibres from stretch receptors of the intrinsic muscles and other sensory receptors.

On the left side, the nerve leaves the vagus in the mediastinum anterior to the arch of the aorta passing behind the ligamentum arteriosum and then posteriorly under the concavity of the arch before passing superiorly to lie in the tracheo-oesophageal groove. It most usually passes behind the inferior thyroid artery and then posterior to the ligament of Berry before passing under or between the fibres of the cricopharyngeal part of the inferior constrictor (Figure 26.6a).²⁴ At this point it lies

Figure 26.4 Lymphatic drainage of the thyroid gland is predominantly to levels VI, IV and III. In metastatic thyroid cancer, levels V and VII may also be affected. Level II is rarely involved and level I almost never.

immediately behind the capsule of the cricothyroid joint (Figure 26.6b).^{25, 26} On the right side (Figure 26.5), the nerve passes posteriorly looping under the first part of the subclavian artery and then has a more oblique course to the tracheo-oesophageal groove. Its relationship with the inferior thyroid artery is more variable:²⁵ in order of decreasing frequency it lies behind, between the terminal branches or occasionally superficial to the artery before entering the larynx in a similar fashion to the left.

The recurrent laryngeal nerve is variable in size ranging from 1.5–4 mm in diameter. It can be identified by its whitish appearance, characteristic longitudinal vessel running along its length and its flattened, rounded surface. In up to 39 percent of cases the nerve divides into two (and occasionally up to six) terminal branches between 6 and 35 mm from the cricoid cartilage.^{25, 27, 28} Special care is therefore required in order not to damage any of these branches during surgical dissection.

A nonrecurrent laryngeal nerve is found in 0.2–0.4 percent of patients.²⁹ It tends to be thicker than a normally sited nerve and is usually associated with a vascular anomaly of the subclavian artery on the right side and transposition of the great vessels on the left side.

The external branch of the superior laryngeal nerve, which supplies the cricothyroid muscle, runs parallel to the superior thyroid vessels in approximately 85 percent of

Figure 26.5 The superior laryngeal nerve branches from the inferior vagal ganglion and divides into a sensory internal branch which perforates the thyrohyoid membrane and a motor external branch which supplies the cricothyroid muscle. The external branch is at risk during thyroid surgery as it may be intimately related to the terminal branches of the superior thyroid artery. The recurrent laryngeal nerve arises from the vagus in the mediastinum and has a longer and more vertical course on the left.

cases. Most often it runs medial to the vessels but it can also run partly lateral, pass between the main branches or lie protected within the inferior constrictor muscle.^{30, 31, 32, 33} The nerve is probably damaged more often than appreciated and is a major cause of changes in voice quality after thyroid surgery.³⁴ The nerve is less likely to be damaged if the branches of the vascular pedicle are ligated on the surface of the gland rather than at the main trunk.

The thyroid gland is under the influence of the autonomic system as well as hormonal control. Sympathetic nerve fibres originate from the superior cervical and stellate ganglia and enter the gland along with the main arteries to form plexuses within the connective tissue between the follicles. Parasympathetic fibres have been shown to originate from the nodose and local vagal ganglia in the rat although the pathways in humans are less well understood. In addition, sensory innervation passes to the jugular, trigeminal and cervical dorsal root ganglia. Pharmacological and physiological studies have shown that there are a multitude of active neuropeptides in the thyroid whose function and interaction is not completely understood but they are likely to have a wide range of roles in the regulation of local blood supply, thyroid hormone synthesis and secretion.^{16, 35}

Microscopic anatomy

The thyroid gland consists mainly of follicular cells, which are arranged in aggregates one cell thick around a central pool of colloid to form follicles (Figure 26.7). The follicles are approximately spherical in shape and between 0.02 and 0.9 mm in diameter.³⁶ A thyroid lobule consists of 20 to 40 follicles and is supplied by a lobular artery.³⁷ The follicular cells have the characteristic cytoplasmic features of an endocrine gland in that they have long segments of rough endoplasmic reticulum and a large Golgi apparatus, for synthesizing and packaging protein, and prominent electron-dense lysosomal bodies. The plasma membranes of the apical and basal layers have separate functions and are kept separate by tight junctions, which bind adjacent cells together. This allows the cell to control the storage of the thyroid hormones in the colloid and their release into the circulation.

When the gland is relatively inactive, the cells are flattened and the colloid is abundant, dense and homogenous in appearance. On prolonged and excessive thyroid stimulating hormone (TSH) stimulation, the follicular cells become hypertrophied and hyperplastic and they adopt a more columnar shape. This cellular enlargement is associated with an increase in the

Figure 26.6 (a) The recurrent laryngeal nerve passing under the lower border of the cricopharyngeal part of the inferior constrictor muscle. (b) The right lamina of the thyroid cartilage has been removed with the thyroarytenoid, lateral and posterior cricoarytenoid muscles to show the lateral border of the cricoid cartilage, the lateral aspect of the conus elasticus and the recurrent laryngeal nerve passing posterior to the articular facet of the cricothyroid joint.

Figure 26.7 The relationship between thyroid follicles and parafollicular cells.

prominence of the intracellular organelles and the development of microvilli on their apical surfaces.³⁸ The microvilli enable the colloid to be absorbed by endocytosis. This is associated with the development of 'reabsorption lacunae' and a reduction in the size of the follicular lumen. This process is also associated with an overall increase in vascularity of the gland.

Each follicle is invested and interlaced with loose connective tissue (stroma) containing a close-meshed plexus of fenestrated capillaries and expanded lymphatics.³⁶ The interfollicle connective tissue spaces are relatively large and contain a collagenous matrix,

fibroblasts, unmyelinated nerve fibres with Schwann cells, fat cells, plasma cells, macrophages and lymphocytes.^{39, 40} The fibroblasts form a highly organized 'neuro-reticular network' by linking their long, thin, branching cytoplasmic processes. These processes are surrounded by autonomic nerve endings in a similar manner to that found in bone marrow and in the submandibular gland. The presence of CD34-positive antigen on the fibroblasts may mean they play an important role in immune surveillance.³⁹

The calcitonin-producing parafollicular cells can be found either singly or in small clumps adjacent to the

stromal aspect of the follicular cells and can be recognized by their polygonal or spindle shape, their relatively large size and their 'light' cytoplasm.⁴¹

PHYSIOLOGY OF THE THYROID

The aim of this section is to provide a brief overview of the physiology of thyroid gland covering formation, storage and secretion of thyroid hormones, their transport to and effect on peripheral tissues and their ultimate metabolism.

Regulation, formation, storage and secretion of thyroid hormones

The formation, synthesis, storage and secretion of thyroid hormones is a complex, highly regulated process under the control of the hypothalamic-pituitary axis (Figure 26.8).⁴² It is also highly dependent on the availability of iodine.

REGULATION OF THYROID GLAND METABOLISM

The secretion of thyrotropin or TSH is mainly under the influence of thyrotropin-releasing hormone (TRH) which is produced in neurons in the paraventricular nucleus of the hypothalamus of the brain. The TRH is then transported along axons and released into the hypothyseal-portal blood circulation by means of specialized nerve terminals where it is carried directly to the basophilic thyrotrophic cells of the anterior pituitary

gland. TRH, and to some extent α -adrenergic agonists, stimulate TSH secretion which in turn cause an increase in iodide uptake in the thyroid gland and in the cellular activities associated with synthesis and secretion of both the precursor and the circulatory thyroid hormones. The thyroid hormones, together with somatostatin and dopamine, inhibit the function of the thyrotrophs.⁴³

Iodine also plays a key role in thyroid physiology and in general has an inhibitory effect on hormonogenesis. By reducing the sensitivity of the thyroid gland to TSH stimulation, it plays an important role in autoregulation of the gland.^{44,45} Iodine in the diet is absorbed from the gastrointestinal tract in the form of inorganic iodide. It is transported in the plasma and erythrocytes and then actively transported into the thyroid and other organs, such as the gastric mucosa, salivary gland, mammary gland, colloid plexus, placenta and skin. Iodide is secreted from these other nonthyroidal organs and then either reabsorbed or lost from the body. Ninety percent of iodide is excreted through the kidneys,³ the rest being lost in the sweat and faeces (and breast milk).

Selenium is also an essential element necessary for thyroid hormone synthesis and the thyroid gland has the highest content of selenium per gram of tissue of any organ. It is an important constituent of several enzymes found in follicular cells, for example glutathione peroxidases, type I 5-deiodinase, thioredoxin reductase and selenoprotein P.⁴⁶ The peroxidases, for example, are responsible for protecting the cells against oxidative damage from by-products of thyroxine metabolism such as hydrogen peroxide (H_2O_2).

THYROID HORMONES

The main hormone secreted by the thyroid gland is 3,5,3',5'-tetraiodothyronine (thyroxine, T_4). It functions mostly as a prohormone and is deiodinated in the target tissue by iodothyronine 5'-monodeiodinase to the more biologically active form 3,5,3'-triiodothyronine (T_3).⁴⁷ Both thyroid hormones are iodinated forms of the amino acid thyronine and contain four or three atoms of iodide, respectively. Twenty to twenty-five percent of the total T_3 production, together with small amounts of reverse triiodothyronine (rT3) and monoiodotyrosine (MIT), are released from the thyroid gland. The biological significance of rT3 and MIT in humans remains unclear.

IODINE TRAPPING

Radioactive iodine (^{131}I) isotope studies have shown that iodide is actively transported from the blood stream into follicular cells through the basal membrane.^{48,49} This is by means of a sodium iodide (Na^+/I^-) symporter whereby two sodium ions are transported for each iodide ion. The inward flux of sodium iodide uptake is stimulated and regulated by TSH in the thyroid gland but not in other

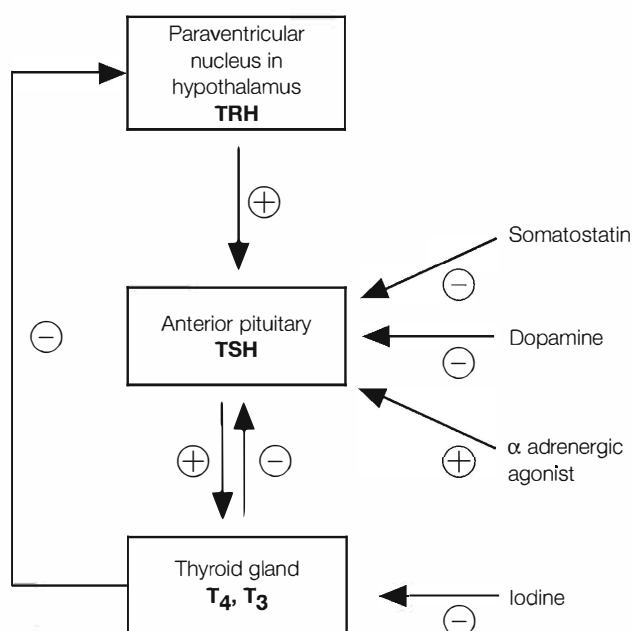

Figure 26.8 Simplified regulatory and biofeedback mechanism of the hypothalamic-pituitary-thyroid axis.

organs that take up iodide. This is not immediate and the presence of the symporter is mostly found in active, cuboidal/columnar form of the cells.^{50,51} It is thought that TSH stimulates increased gene expression and protein synthesis of the Na^+/I^- symporter although there are also intrinsic factors which influence its properties which remain undetermined.^{7, 49, 52}

The accumulated iodide in the follicular cells is then transferred to the apical plasma membrane down an electrochemical gradient. TSH stimulation increases adenosine triphosphate (ATP) and ATPase activity at the apex of the cell increasing the efflux of iodide into the colloid down a further electrical gradient.

IODIFICATION OF THYROGLOBULIN

Thyroglobulin is a large alpha-protein and is the major constituent of colloid. It is only synthesized by the follicular cells⁵³ and, once formed, it is incorporated into

apical vesicles for export into the follicular lumen. At the apical membrane thyroid peroxidase uses hydrogen peroxide and iodide to oxidize and organify the thyroglobulin protein in a TSH-sensitive cAMP-mediated process.⁴ This creates the bound precursor thyroid hormones, namely MIT and diiodotyrosine (DIT), as well as some T_4 and T_3 , where they can be stored until required (Figure 26.9).⁵³

SECRETION OF THYROID HORMONE

Stimulation of the thyroid gland by TSH leads to small droplets of colloid being taken up into the follicular cells by micropincocytosis to form endosomes or less commonly in bulk as colloid droplets (CD).^{54,55} Both the endosomes and colloid droplets fuse with lysosomes⁵⁶ and proteolysis takes place. This results in the release into the cytoplasm of the peptides MIT, DIT, thyroxine and triiodothyronine. MIT and DIT are then rapidly

Figure 26.9 Summary of the key steps in the biosynthesis and secretion of thyroid hormone: (1) Iodide is transported by a symporter through the basement membrane of the follicular cell. (2) Polypeptide chains are synthesized on the surface of the endoplasmic reticulum (ER) before being transported into the ER lumen. (3) Dimers are formed and the polypeptide chains are then folded and modelled prior to the addition of carbohydrate units in the Golgi apparatus to form the thyroglobulin (TG) molecules. Newly formed thyroglobulin is then transported to the lumen in apical vesicles (AV). (4) Iodination of thyroglobulin takes place at the apical membrane prior to (5) coupling of iodotyrosyl precursors by thyroperoxidase to form MIT, DIT and small amounts of T_4 and T_3 on the surface of the thyroglobulin molecule. (6) Colloid is absorbed by micropincocytosis to form endosomes and also taken into the cell to form colloid droplets. (7) The thyroglobulin in the endosomes and colloid droplets undergoes proteolysis by lysosomal enzymes releasing iodide and DIT and MIT. (8) The iodide is recycled and the MIT and DIT peptides undergo further deiodination by 5' deiodinase (9) to form T_4 and T_3 which are then released into the bloodstream.

deiodinated by microsomal iodotyrosine deiodinase and iodide is released which is then recycled or excreted from the cell into the circulation. The efflux of iodide from the basolateral aspect of the cell is a regulated Ca^{+} -dependent process, the details of which have not been fully determined. It is clear, however, that it is different from the apical mechanism as it does not involve cAMP.

Once the thyroid hormones have been released from the thyroglobulin molecule, they are rapidly released from the cell into the circulation although the exact mechanism is not known.⁵³ Thyroglobulin is mostly degraded although some is recycled back into the lumen and small amounts of both the iodinated and uniodinated forms are also released into the circulation. It can also reach the circulation by being transported from the apical to the basolateral cell membrane within vesicles. Its release into the bloodstream is by a TSH-stimulated process known as transcytosis.⁴ The concentration of thyroglobulin in the serum is ultimately determined by the balance between the rate of synthesis and the rate of metabolism by hepatocytes.⁵⁷ Serum levels vary from undetectable to 40 ng/mL in normal subjects (Table 26.2).⁵⁸ They are elevated in newborn infants and also in response to TSH and TRH stimulation, thyroid inflammation, thyrotoxicosis and metastatic thyroid carcinoma.⁵⁹

THYROID HORMONE TRANSPORT PROTEINS

Over 99 percent of the serum thyroid hormones are bound to transport proteins. Although not essential for hormone action, they appear to be required for the smooth functioning of the thyroid gland. They are thought to have three main functions: (1) extrathyroidal storage of T_4 and T_3 ; (2) buffering and protection against the effect of excessive thyroid hormones; and (3) controlled release of the hormones into the very small free hormone pool (<0.1 percent of serum T_4 and 0.3 percent of T_3) that is made available to peripheral cells.⁶⁰ A variety of proteins take part in this transport system including thyroxine-binding globulin (TBG), transthyretin (TTR or T_4 -binding prealbumin), albumin and lipoproteins. TBG, TTR and albumin are all produced by hepatocytes.

TBG is one of the minor components of the alpha-globulin family. It carries 70 percent of the circulating

T_4 and T_3 and has the highest affinity of all the serum proteins that bind T_4 and T_3 . It is thought that it has no other physiological function other than binding these hormones in contrast to the other major carrying proteins. Transthyretin binds 10–15 percent of the thyroid hormones and is thought to be responsible for the more immediate delivery of the hormones to cells as it dissociates from the hormone more quickly. It forms the major thyroid binding protein in the CSF, where it is produced by the choroid plexus. It is thought, however, that more biologically active thyroid hormone is probably delivered to the central nervous system through the capillary network. Albumin carries a multitude of small molecules including approximately 15–20 percent of the circulating T_4 and T_3 in spite of having a very low affinity for these hormones. Lipoproteins, and in particular high-density lipoproteins, are responsible for carrying 3–6 percent of the thyroid hormones. Fatty acids and other anions, including chloride, reduce the binding of T_4 . They may have a special effect in thyroid hormone physiology as the transport proteins are internalized by specific cell-surface receptors.⁶¹

INTRACELLULAR EFFECTS AND METABOLISM OF THYROID HORMONES

On reaching the target tissue via the circulation, thyroid hormones enter the cell either by diffusion through the plasma membrane or by active or facilitated transport after binding to specific cell surface sites. The thyroid hormone is then transferred to cytosol binding sites and to the 5'-deiodinase on the endoplasmic reticulum (and/or plasma membranes, although this has not been determined for all cell types) where most of the T_4 is deiodinated to form T_3 . An equal amount of rT_3 is also formed but its functional significance is uncertain.⁵⁹ It may have a regulatory role in thyroid hormone metabolism but has no calorogenic activity and is rapidly deiodinized to DIT (Table 26.3).^{3, 59}

This intracellular T_3 acts by binding to specific nuclear receptors.^{62, 63, 64} These receptors are members of the large *c-erbA* superfamily that includes receptors for steroid hormones, vitamin D, retinoic acid, and peroxisomal proliferator activators responsible for regulating the expression of target genes.⁶⁵

A detailed description of the effect of thyroid hormones on the different tissues is beyond the scope of this chapter. Most of the effects of intracellular T_3 are related to the stimulation of O_2 consumption in almost all metabolically active tissues with the exception of the adult brain, testes, uterus, lymph nodes, spleen and anterior pituitary. Increased metabolism is associated with increased nitrogen secretion. Endogenous protein and fat are catabolized, resulting in weight loss if food intake is not increased. High levels of thyroid hormones cause the following: significant skeletal muscle catabolism and

Table 26.2 Typical normal serum levels for thyroid hormones. Local laboratory reference ranges and assay techniques may vary.

	Metric (SI units)
TSH	0.3–4.0 mU/L (~1–15)
T_4	4–11 $\mu\text{g/dL}$ (60–140 nM)
Free T_4	0.7–2.1 ng/dL (10–25 pM)
T_3	75–175 ng/dL (1.1–2.7 nmol/L)
Free T_3	0.2–0.5 ng/dL (0.2–0.7 nM)

Table 26.3 Properties of iodothyronine deiodinase isozymes.

Property	Type I 5'-deiodinase	Type II 5'-deiodinase	5-Deiodinase
Main function	Bioactivation of T ₃	Local intracellular bioactivation of T ₃	Inactivation and degradation of iodothyronines + recycling of iodide
Substrate preference	rT ₃ >> T ₄ >> T ₃	T ₄ > T ₃	T ₃ (sulphate) > T ₄
Tissue distribution	Thyroid, kidney, liver, euthyroid CNS	CNS, pituitary, brown adipose fat	Almost every tissue
Subcellular location	Liver: endoplasmic reticulum Kidney: basolateral membrane	Microsomal membranes	Microsomal membranes Liver: endoplasmic reticulum

consequent weakness, hypercalcaemia and a degree of osteoporosis from mobilization of bone protein and a slight rise in body temperature due to the increased heat production. Thyroid hormones also potentiate the effect of growth hormone on the tissues and are essential for normal growth and skeletal development.

Deactivation of the thyroid hormones involves further deiodination by 5-deiodinase into diiodothyronine, monoiodothyronine and thyronine. This pathway is important in the regulation and bioinactivation of the thyroid hormones and the recycling of iodide. Alternatively, the thyroid hormones can be deactivated in the liver by sulphaconjugation by cytosolic sulphotransferases and the products are then excreted in the bile. These are mostly reabsorbed in the enterohepatic circulation although a small amount is lost from the body.

Parafollicular cells (C cells)

Parafollicular cells secrete calcitonin in response to elevated serum levels of calcium or gastrin. A total thyroidectomy does not always abolish calcitonin secretion as it can be produced by other organs, such as the brain, gastrointestinal tract, urinary bladder, thymus and lungs.⁶⁶ Calcitonin lowers serum calcium and phosphate levels by inhibiting the osteoclastic resorption of bone and enhancing the excretion of calcium by the kidneys. Its physiological importance is debatable as parathyroid hormone and vitamin D are thought to be more important in calcium haemostasis.⁶⁷

Deficiencies in current knowledge and areas for future research

We only have a broad understanding of the the hugely complex intracellular and extracellular control mechanism of thyroid glandular tissue and the mechanisms whereby this homeostasis breaks down in different thyroid diseases, which can often lead to the formation of a goitre. In addition, we need to develop a greater understanding of how the thyroid hormones interact with the end-organ tissue receptors to produce the wide variety of systemic effects. A better understanding of this interaction may lead to compounds being developed that have selectively beneficial effects, such as lowering cholesterol and weight reduction, while avoiding the adverse cardiac effects.

SEARCH STRATEGY

Information for this chapter was gathered by searching Medline using the key words thyroid, thyroid function tests, radionuclide scan, thyroid stimulating hormone, thyroxine, endocrine disease.

INTRODUCTION

Development and function

The thyroid gland is a key endocrine organ located in the head and neck region. It develops from the first branchial pouch during foetal development and descends to its normal position in the neck above the suprasternal notch. The path of the gland's descent is marked by the thyroglossal duct. The normal gland is commonly asymmetrical and the asymmetry of its two lobes is enhanced with thyroid enlargement.

The two lobes of the thyroid, connected by the fibrous isthmus, contain follicular cells arranged in a follicular pattern around colloid where thyroid hormones bound to thyroglobulin are stored. The stroma of the thyroid contains fibrocytes and occasional lymphoid cells.

The main function of the gland is the production of thyroxine (T4) and triiodothyronine (T3) by the iodination of tyrosine residues in the thyroglobulin molecule within the thyroid follicular cells. The presence of peroxidase and coupling enzymes is essential for this process, as is an adequate supply of dietary iodine and a functioning NaI symporter system. T4 and T3 remain contained within the thyroglobulin molecule until, under thyroid stimulating

hormone (TSH) stimulation, the thyroglobulin containing colloid is endocytosed by the thyroid follicular cells, the resulting endosomes fused with lysosomes containing hydrolases and T4 and T3 released by the hydrolyzation of the thyroglobulin and then secreted into the circulation. It is now believed that little T3 is produced by the normal thyroid, the majority of T3 production (80 percent) occurring in the peripheries by conversion of T4 to T3 through the process of deiodination. Iodine uptake and T4 and T3 release are under the control of the hypothalamus and pituitary gland with a negative feedback system. Thyroid releasing hormone (TRH) and TSH levels rise with falling serum T4 and T3 levels.

T4 and T3 are hormones that are predominantly bound in the serum with T4 conversion to T3 occurring at the peripheries, T3 being the active hormone. In conditions of ill-health and under the influence of certain drugs, such as propranolol, the conversion of T4 to the inactive hormone reverse T3 (rT3) occurs.

The parafollicular or C cells within the thyroid secrete the hormone calcitonin, the function of which is unclear in man.

Disorders of the thyroid may result from developmental failures, abnormalities of hormone production and structural changes which may or may not be

Table 27.1 Biochemical tests in thyroid disease.

	FT4	FT3	TSH	TSI	Anti-TPO	Anti-microsomal	Anti-thyroglobulin	Thyroglobulin	Calcitonin
Euthyroid goitre	Normal	Normal	Normal	Normal	Normal	Normal	Normal	Normal	Normal
Autoimmune thyrotoxicosis	Raised	Raised	Low	Raised	Raised	Normal	Normal	Raised	Normal

Ca thyroid	Normal	Normal	Normal	Normal	Normal	Normal	Normal	Raised	Normal
Medullary Ca thyroid	Normal	Normal	Normal	Normal	Normal	Normal	Normal	Normal	Raised

accompanied by changes in function. Blood tests measuring hormone production or the antibodies associated with disordered function may be measured *in vitro* (Table 27.1). Structural and local functional changes within the gland may be identified using a variety of imaging techniques (Table 27.2).

***In vitro* tests of thyroid function**

The standard tests of thyroid function are widely available. Since only 0.02 percent of T4 and 0.3 percent of T3 circulate in the unbound form, and it is the free hormones that are physiologically active, measurements of free T4 and free T3 levels most accurately indicate a patient's thyroid status.

The single most useful measure of thyroid function is the ultrasensitive measurement of TSH. A normal TSH measurement is a good indicator of normal thyroid function except in the rare situation of pituitary dysfunction. Changes in the TSH level will precede changes in FT4 and FT3 levels and TSH levels above or below the normal range indicate developing or recovering thyroid pathology.

Autoantibodies associated with thyroid pathology may also be measured. Identification of raised serum antibody levels to thyroglobulin, thyroid peroxidase, microsomes and the TSH receptor will significantly facilitate the accurate diagnosis of thyroid disease. The measurements of these antibodies are constantly being refined to avoid cross-reactivity. An excellent review of the interpretation of thyroid function tests is found in the review article of Dyan.¹

Imaging investigations

ULTRASOUND

Ultrasound (US) can differentiate solid from cystic lesions and can identify cysts as small as 2 mm. It is performed

using a 12 MHz transducer that is optimal for high resolution imaging though a 5 MHz transducer may be needed for very large goitres. Colour flow or power Doppler is helpful in assessing vascularity. US coupled with fine needle aspiration cytology (FNAC) provides further information.²

Computed tomography

Computed tomography (CT) is used to characterize large thyroid masses, to assess invasion of adjacent structures and identify metastatic nodes in the neck and mediastinum. Collimation of 3–5 mm is used and intravenous contrast medium administered. This should not be given until the thyroid function tests have been measured. The normal thyroid is of higher attenuation than muscle.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is also used to assess large tumours, especially those with suspected mediastinal extension with 3 mm axial, coronal and sagittal T1 and T2 weighted sequences. Postcontrast fat suppressed sequences may be helpful. The normal thyroid is of low signal on T1 weighted images, relative to muscle and intermediate signal on T2 weighed images. The multi-planar capability is helpful and although the specificity of MRI differs little from CT, the lack of the need for iodinated contrast is an advantage.

Radionuclide imaging

A variety of radiopharmaceuticals are suitable for imaging the thyroid and thyroid pathologies (Table 27.2). The radiopharmaceuticals include those that are taken up by the thyroid by normal pathways, such as ¹²³I iodine, ¹³¹I iodine and ^{99m}Tc pertechnetate, as well as those that are taken up into pathological processes, such as ^{99m}Tc V dimercapto succinic acid (DMSA). ^{99m}Tc pertechnetate has the advantage of availability and low cost for routine thyroid imaging. The disadvantage is that unlike ¹²³I iodide it is trapped but not organified by the thyroid.³

Table 27.2 Imaging investigations in thyroid disease.

	Goitre	Graves	Toxic nodule/s	Viral thyroiditis	Hypothyroidism	Ectopic	Ca thyroid differentiated	Ca thyroid dedifferentiated	MTC	Lymphoma

THYROID PATHOLOGY

A summary of thyroid pathology is provided as follows.

- Developmental disorders:
 - maldescent:
 - lingual;
 - sublingual;
 - subhyoid.
 - maldevelopment:
 - absent thyroid;
 - aplastic, hypoplastic thyroid lobe;
 - thyroglossal cyst.
- Disorders of function:
 - hyperthyroidism:
 - toxic diffuse goitre (Graves' disease);
 - solitary toxic nodule;

 - invasive (Riedel's thyroiditis, amyloid, haemochromatosis);
 - malignant (lymphoma).

Developmental disorders

Maldevelopment of the thyroid is usually detected in childhood following the discovery of an abnormal swelling at the base of the tongue or in the sublingual area. Midline swellings above the normal position of the thyroid may be due to a thyroglossal duct cyst. Most occur at (15 percent) or immediately below (65 percent) the hyoid bone. Suprahyoid cysts occur in only 20 percent of cases.

Structural abnormalities of the thyroid with normal function

A common presentation of patients with thyroid disorders affecting the structure of the gland is the awareness of a nodular or generalized swelling of the thyroid.

DIFFUSE GOITRE

Euthyroid diffuse goitre is not an uncommon finding in women. The thyroid may enlarge during puberty, pregnancy and at the time of the menopause. Women commencing the contraceptive pill may also become aware of thyroid swelling. Although these diffuse swellings of the thyroid are usually transient, some women may have permanent swellings of their thyroid which are not associated with thyroid dysfunction.

Patients with a diffuse goitre and a family history of goitre may have a congenital dyshormonogenesis leading to a partial failure of iodide organification. This is commonly associated with deafness in Pendred's syndrome. Despite the organification defect, these patients are commonly euthyroid.

NODULAR GOITRE

Palpation has proven to be unreliable in accurately assessing the structure of the thyroid, as apparently solitary nodules are frequently part of multinodular change⁴ and many ultrasound identified nodules are not palpable. Nodules within the thyroid may be cystic or solid. Cystic lesions may be simple or complex and rapid swelling accompanied by discomfort is usually indicative of haemorrhage. Colloid nodules are a common benign cause of thyroid swelling in patients with multinodular change within the gland.

Adenomas represent 10 percent of thyroid nodules and are either follicular (micro-, normo- or macrofollicular) or nonfollicular. Thyroid cancer is an uncommon malignancy with 900 new cases reported annually in the UK and the histology includes papillary (60–80 percent), follicular (10–18 percent), anaplastic (3–10 percent) and medullary (4–8 percent).

Papillary carcinomas occur in 30–40 year olds and tend to be well differentiated, slow growing with an excellent prognosis and an average size of 1.5 cm. Tumours presenting in older age groups are often poorly differentiated, invade the larynx and oesophagus, and have a poor prognosis. Papillary carcinomas are not uncommonly multifocal and are bilateral in 10 percent of cases. Spread to lymph nodes is common, occurring in up to 70 percent of cases. Follicular carcinomas are commoner in females and have a peak incidence in the fifth decade. They are solitary, slow growing encapsulated tumours and resemble adenomas. The more aggressive tumours extend outside the gland and have a poor prognosis. Lymph node involvement is unusual (5–13 percent) but haematogenous spread to bone, liver and brain is not uncommon. Medullary carcinoma is the most uncommon subtype. It originates from C cells and produces calcitonin. It may either be sporadic (75–90 percent) or familial as part of multiple endocrine neoplasia (MEN) 2a or 2b syndrome, or familial medullary thyroid cancer. The tumours associated with MEN occur in younger patients (mean age 35 years) and are bilateral in 80 percent of MEN 2b, but bilateral in only 20 percent of sporadic cases.

MULTINODULAR GOITRES

Adenomatous or colloid multinodular goitres are common, occurring in 3–5 percent of the general population. Haemorrhage, fibrosis and calcification are found within goitres and the incidence of malignant transformation is approximately 7.5 percent.

Patients with a family history of goitre should be suspected of having dysmorphogenesis. In geographical regions of iodine deficiency, endemic goitre remains common.

Structural abnormalities with abnormal function

HYPERTHYROIDISM

Toxic diffuse goitre (Graves' disease)

This is the commonest cause of thyrotoxicosis in the UK. The clinical picture of a diffuse goitre and dysthyroid eye disease is pathognomonic of Graves' disease but only 50 percent of patients present with dysthyroid eye disease, and dysthyroid eye disease may precede or succeed the development of thyrotoxicosis by up to two years.

Solitary toxic nodule

Clinical examination of the thyroid will frequently determine the presence of a nodule within the thyroid. In the presence of thyrotoxic symptoms, a presumptive diagnosis of solitary toxic nodule can be made. However, this diagnosis requires confirmation with imaging studies as clinically single nodules are not infrequently part

of impalpable multinodular change within the thyroid. Graves' disease in an asymmetrical thyroid may also be mistaken clinically for a unilateral toxic nodule. Similarly, the rare coexistence of thyroid carcinomas in patients with Graves' disease may lead to a misdiagnosis of a solitary toxic nodule if clinical palpation alone is relied upon.

Multiple toxic nodules

The association of clinical thyrotoxicosis in a patient with a palpable multinodular goitre will usually result from the development of one or more autonomous nodules in a multinodular gland. The presence of palpable nodule(s) in a thyrotoxic patient does not confirm a diagnosis of toxic nodular goitre however, as Graves' disease may occur in a multinodular goitre.^{5,6} Since the management of Graves' thyrotoxicosis and toxic nodular disease is different, with Graves' patients usually being offered a prolonged trial of antithyroid medication, the correct diagnosis is essential to ensure optimal management. Similarly, small multinodular goitres with toxic nodules may be difficult to palpate and a misdiagnosis of Graves' disease may be made.

Transient hyperthyroidism

Patients may present with transient episodes of hyperthyroidism associated with transient swellings of the thyroid. Subacute viral thyroiditis or De Quervain's thyroiditis is typically preceded by a viral upper respiratory tract infection followed by acute painful swelling of the thyroid and symptoms of thyrotoxicosis. Whilst the swelling is typically bilateral, unilateral disease has been described. The condition is self-limiting and usually resolves within one month of onset. Post-partum thyroiditis affects 7 percent of women after delivery. Unlike subacute viral thyroiditis, the goitre is painless and is associated with a transient episode of hyperthyroidism usually followed by a short period of hypothyroidism. The condition generally resolves spontaneously although patients may remain permanently hypothyroid after the episode.

Hyperthyroidism associated with cancer of the thyroid

Thyroid cancer is generally characterized by being well differentiated with thyroid follicular cells retaining many of the properties of normal thyroid follicular cells including the ability to take up iodine. Rarely, in patients with disseminated large volume metastatic disease, the bulk of tumour may result in the overproduction of T4 leading to overt thyrotoxicosis. This rare condition is usually associated with widespread bone metastases.

HYPOTHYROIDISM

Hypothyroidism may rarely be congenital associated with agenesis of the thyroid. More commonly, it is associated

with the presence of autoantibodies leading to juvenile or adult Hashimoto's thyroiditis. The changes in the structure of the thyroid resulting from the autoimmune condition are generally nodular although the pattern of change may be diffuse, mimicking those seen in Graves' disease. In patients with established Hashimoto's thyroiditis, maintained on adequate replacement doses of thyroxine, a rapid increase in size of the goitre should be investigated urgently as a B cell lymphoma of the thyroid may develop within a Hashimoto's goitre.

INVESTIGATION OF ABNORMAL DEVELOPMENT AND STRUCTURE

In vitro investigations

DEVELOPMENTAL ABNORMALITIES

The most important role of *in vitro* studies of thyroid function in patients with developmental abnormalities of the thyroid gland, such as a lingual thyroid and thyroglossal cysts, is to confirm normal thyroid function. A TSH value in the middle of the normal range excludes any abnormality of function.

DIFFUSE CHANGE

The history of a patient with a diffuse goitre may often give insight into the cause of the goitre. Recent changes in the pituitary ovarian axis in women or a family history of goitre will direct further investigations. Confirmation of normal thyroid function with a TSH in the middle of the normal range is essential to exclude early structural change preceding overt biochemical changes. A TSH level towards the upper end of the normal range may indicate developing hypothyroidism in a patient with a familial dysmorphogenesis or developing Hashimoto's thyroiditis. A TSH in the lower end of the range may indicate a resolving viral thyroiditis, or developing autoimmune thyrotoxicosis (Graves' disease). Serial measurements of thyroid function are indicated in patients with TSH values at the upper or lower end of the range to determine whether a drift in thyroid function is occurring.

Autoantibody measurements are also indicated to identify covert Hashimoto's thyroiditis with elevation of the antithyroid peroxidase antibody, antimicrosomal antibodies and antithyroglobulin antibodies or early Graves' disease in a patient with raised TSH receptor antibodies.

NODULAR CHANGE

It is essential to determine the biochemical status of any patient presenting with one or more thyroid nodules as part of the diagnostic strategy for assessing nodules.

Normal thyroid function, as evidenced by a normal TSH value, excludes toxic nodular change or conversely, developing Hashimoto's thyroiditis. In patients with a family history of goitre and or hypothyroidism, it is appropriate to measure thyroid autoantibody levels, specifically antithyroid peroxidase antibody and antithyroglobulin antibody. If levels of these antibodies are raised, then as with the patient presenting with a diffuse goitre, the patient is at risk of developing Hashimoto's thyroiditis in the future and requires regular monitoring with thyroid function tests. A low normal TSH value with a low normal FT4 level may occasionally be misinterpreted as 'sick euthyroid syndrome'. A further FT3 measurement may indicate high normal values consistent with a developing autonomous nodule. Serial thyroid function tests together with imaging are indicated.

Any patient with normal thyroid function and a palpable nodule requires urgent further investigation to exclude malignancy as the cause of the nodular change.

Imaging investigations

DEVELOPMENTAL DISORDERS

Maldescent of the thyroid is usually detected in childhood following the discovery of an abnormal swelling at the base of the tongue or in the sublingual area. A ^{99m}Tc thyroid scan will clarify the location of the thyroid and avoid the necessity for biopsy or inadvertent excision of ectopic thyroid tissue. A lingual thyroid is easily identified on CT as a high attenuation mass within the tongue base at the foramen caecum. Midline swellings above the normal position of the thyroid may be investigated using ultrasound, which will determine the cystic nature of a thyroglossal duct cyst. MRI is the best imaging modality for assessment of cradial extension using T2 weighted sagittal imaging. CT and MRI show a characteristic midline cystic mass nestled within the infrahyoid strap muscles. A ^{99m}Tc thyroid scan will confirm the normal position of the thyroid and the absence of functioning thyroid tissue in the cyst. As ectopic thyroid tissue has a higher incidence of malignant transformation compared with normally situated tissue, excision of such tissue is usually performed.

Disorders of structure

NODULAR CHANGE

Palpation has proven to be unreliable in accurately assessing the structure of the thyroid as apparently solitary nodules are frequently part of multinodular change.⁴

An ultrasound scan of the thyroid in a patient presenting with an apparently solitary nodule will

accurately determine whether the nodule is truly solitary, and will also determine the cystic or solid nature of the nodule and facilitate biopsy. Palpable nodules that are identified as cystic on ultrasound can be aspirated under ultrasound guidance and cytology performed on the aspirate. If the cyst reaccumulates, or if there is evidence of a complex cyst, surgery should be performed in view of the risk of malignancy. Rapid onset swellings associated with pain are frequently shown on ultrasound to have the classic appearance of haemorrhage into a cyst with internal debris, septation or both⁷ and again this may be confirmed with FNAC.

On ultrasound, microfollicular and nonfollicular adenomas are hypoechoic whereas macrofollicular adenomas are hyperechoic. Most homogeneous hyperechoic lesions are benign but 50 percent of adenomas are isoechoic with a hypoechoic capsule. On colour Doppler, adenomas have a vascular rim and central vascularization is seen in both autonomous adenomas and carcinomas. The features suggestive of a benign adenoma include cystic lesions without solid areas, homogeneous hyperechoic masses, thin hypoechoic rims, multiple lesions and the presence of egg shell calcification. Signs of malignancy include infiltrative margins, papillary solid areas in a cystic lesion, central vascularization, inhomogeneous echo pattern and associated lymphadenopathy.

On CT, follicular adenomas are either solid enhancing masses or have areas of cystic degeneration and calcification.

Papillary carcinomas on ultrasound are hypoechoic with irregular central vascularization and microcalcification. On CT, these tumours are solid with cystic areas and contain punctate or amorphous calcification, while on MRI they are isointense with muscle on T1 and intermediate to high intensity on T2-weighted sequences.⁸ Distant metastases to lung and bone occur in 5–7 percent of patients.

Follicular carcinomas on CT and MRI are usually well-defined solid nodules with no cystic component, with the more aggressive showing local invasion. On ultrasound these tumours are iso- or hypoechoic with central vascularization of 90 percent.

Medullary thyroid cancers on CT and MRI are solid with coarse or psammomatous calcification. Local invasion is not uncommon and spread to neck and mediastinal nodes occur in up to 50 percent of cases with distant metastases in liver, lung and bone in 15–25 percent. On ultrasound the lesions are hypoechoic with ill-defined margins and microcalcification.

It is not possible to confidently distinguish between an adenoma and carcinoma on ultrasound and FNAC should be undertaken if there is any doubt. FNAC has been shown to be simple and cost-effective,⁹ with reported positive predictive value for malignant disease of 94 percent and a false negative and false positive rate of 2.7 and 5.4 percent, respectively. The role of radionuclide imaging in the diagnosis of the solitary solid nodule is

controversial.¹⁰ Whilst fine needle aspiration will usually yield results that guide management, some problems may exist in interpreting the results. Sampling errors may occur in multinodular goitres and it is only the radionuclide scan that will ensure that nonfunctioning nodules are sampled. A follicular lesion will require surgical removal to determine whether the lesion is a benign follicular adenoma or a follicular carcinoma. However, follicular lesions, if 'hot' on radionuclide imaging with ^{99m}Tc or ¹²³I, have a low likelihood of malignancy (less than 4 percent in a review of 4000 patients)^{11, 12} and if the TSH value is towards the lower end of the normal range, may safely be kept under observation whilst the TSH level continues to be monitored. If there is no downward trend in the TSH value, then excision should be performed. Solitary solid nodules will also require further investigation with FNAC under US control if the thyroid function tests show no evidence of developing autonomous function with a low normal or abnormally low TSH value in the presence of high normal T4 and/or T3 levels.

Other radiopharmaceuticals have been investigated in an attempt to reduce the number of unnecessary operations performed in patients with follicular lesions. The uptake of both ^{99m}Tc Sestamibi (MIBI) and ²⁰¹Tl has been assessed and although the uptake of both tracers has been shown to be generally higher in follicular carcinomas than follicular adenomas, there is no clear cut off in the uptake values to distinguish benign from malignant lesions.^{13, 14} If malignancy is diagnosed on FNAC, ultrasound, CT or MRI may be used to assess the locoregional lymph nodes prior to surgery. Care should be taken with use of contrast media during CT imaging, as this will block the uptake of subsequent therapy dose of ¹³¹I iodine used to ablate remaining thyroid tissue following surgery.

Following the diagnosis of Ca thyroid and the surgical resection of the thyroid and involved lymph nodes, ¹³¹I iodine is used to ablate remnant thyroid tissue and then, in tracer doses, to image for recurrent disease.

A whole body scan using ¹³¹I iodine as the tracer will usually identify recurrent disease, but it is essential that the TSH level is elevated at the time of administration of radioiodine necessitating the discontinuation of thyroid supplements for a minimum of four weeks for thyroxine and two weeks for triiodothyronine. Recently, an injectable form of recombinant TSH has been licensed for use in Ca thyroid to administer with radioiodine. If the recurrent disease is radioiodine avid on tracer imaging, a therapy dose of radioiodine may be given (5–7 GBq). Radioiodine therapy is continued at six-monthly intervals until the tracer scan clears and the thyroglobulin level falls.

Although iodine-based radionuclides remain the main agents in use for nuclear medicine imaging in the follow-up of differentiated thyroid cancer, there are other radiopharmaceuticals that can be used. Progressive

dedifferentiation of a thyroid cancer commonly leads to a loss of iodine-concentrating ability by the tumour cells. In addition, the requirement to discontinue thyroxine or triiodothyronine for a period of time prior to iodine imaging may delay imaging in patients who develop new masses. The TSH rise associated with discontinuing thyroid replacement medication may also accelerate tumour growth in aggressive tumours. There is, therefore, a role for alternative imaging agents to localize dedifferentiating tumours and which permit imaging whilst the patient is still on thyroxine. The most useful include ^{201}Tl thallium, $^{99\text{m}}\text{Tc}$ MIBI, $^{99\text{m}}\text{Tc}$ tetrofosmin (Myoview) and ^{18}F fluorine fluorodeoxyglucose (FDG)-positron emission tomography (PET).

These agents are used in conjunction with anatomical imaging methods, ultrasound, CT and MRI.

The sensitivities of ^{201}Tl thallium and $^{99\text{m}}\text{Tc}$ tetrofosmin are comparable with that of ^{131}I iodine for detecting distant metastases (0.85, 0.85, 0.78), although ^{131}I iodine is more sensitive than the other two for detecting post-surgical residual thyroid tissue.¹⁵ Scintigraphic imaging with ^{201}Tl thallium has been thought to reflect the abnormal DNA characteristic of poor prognosis in differentiated thyroid carcinoma. Nakada *et al.* found that ^{201}Tl thallium uptake was significantly higher in patients with aneuploidic nuclear DNA ($p < 0.01$). These patients went on to exhibit the aggressive clinical behaviour characteristic of metastatic tumours.¹⁶

When compared to ^{201}Tl thallium, MIBI has been proved to be clinically more useful in detecting lung, lymph node and bone metastases from differentiated thyroid carcinoma, as image quality is better. The overall sensitivity of the two techniques is not, however, significantly different.¹⁷ The superiority of MIBI in detecting lymph node disease before initial ^{131}I iodine treatment was confirmed by Ng *et al.*¹⁸ who also noted that MIBI is not as sensitive as ^{131}I scanning for thyroid remnants or lung metastases.

Both MIBI and ^{201}Tl thallium yield high specificity and positive predictive value for residual thyroid cancer in patients with increased risk of recurrence after ^{131}I therapy who have had negative ^{131}I scans. Both imaging agents have been shown to detect residual cancer and cause a change in management in more than half the patients in whom conventional imaging techniques were unreliable.¹⁹

The main value of ^{18}F fluorine FDG-PET in the management of thyroid carcinoma patients, in common with the other methods above, lies in its ability to demonstrate metastatic sites after negative iodine scanning. Its accuracy is high, especially for cervical lymph nodes where it has proved particularly helpful for directing surgical management. It can also identify metastases in the mediastinum, lungs and bone. Studies on patients with thyroglobulin positive/iodine scan negative disease gave sensitivities of 94 percent²⁰ and 71 percent²¹ for detecting iodine negative disease. The increased metabolic activity of dedifferentiating aggressive

tumours would explain the high ^{18}F fluorine FDG-PET uptake compared with much lower uptake seen in iodine avid tumours.

Patients with medullary thyroid cancer and rising calcitonin levels may be imaged with ultrasound, CT or MRI to localize respectable disease. In some patients, however, the recurrent disease volume is small and radionuclide imaging may be helpful in detecting areas of recurrence (Table 27.2). Uptake by ^{123}I metaiodobenzylguanidine (MIBG) will identify patients who may respond to therapy with ^{131}I MIBG.

Multinodular goitres

The appearance of goitres on CT or MRI is variable, depending on the histology, with calcification best seen on CT. On MRI there is variable signal intensity due to fibrosis (low signal on T1 and T2W), colloid (low or high signal on T1, high signal on T2W), blood (variable signal on T1 and T2W) and calcium (low signal).

On ultrasound, a goitre is more echogenic than normal thyroid and as it increases in size it becomes more inhomogeneous with ill-defined posterior borders. It may be difficult to visualize the full extent on ultrasound.

Euthyroid goitres may be imaged by CT or MRI prior to surgery to assess the presence of retrosternal extension and, in patients with pressure symptoms, the degree of tracheal deviation or compression.

Patients with a family history of goitre and suspected dysthyroidism may be investigated using a combination of ^{123}I iodine and perchlorate. Failure of organification of ^{123}I iodide occurs and the nonorganified iodine is displaced from the gland when perchlorate is administered.

INVESTIGATION OF STRUCTURAL ABNORMALITIES WITH ABNORMAL FUNCTION

In vitro investigations

AUTOIMMUNE THYROTOXICOSIS (GRAVES' DISEASE)

Patients with Graves' disease usually present with classical symptoms of thyrotoxicosis and the clinical findings of a diffuse goitre. The measurement of thyroid function will confirm elevations of FT4, and occasionally FT3, together with a suppressed TSH level. The size of the goitre often correlates with the severity of the biochemical abnormality. The findings of raised TSH receptor antibody levels (TSHrA or TSI) will confirm the diagnosis in the majority of cases although 10 percent of patients will not demonstrate elevated antibody levels. It is believed that this 10 percent represents a failure of antibody detection and newer assays claim a higher antibody detection rate. Patients who have been treated with antithyroid medication may not have elevated antibody levels as the immunosuppressive action of these agents becomes

effective. Thyroid peroxidase antibodies are also elevated in the majority of patients.

TOXIC NODULAR GOITRE

Thyroid function tests will confirm the biochemical status of the patient with a nodular goitre and a clinical suspicion of thyrotoxicosis. Elderly patients or patients with early disease may be asymptomatic however, and any patient with a nodular goitre and a low normal or suppressed TSH is at risk of developing frank thyrotoxicosis and should be regularly monitored. Whilst the classical pattern of elevated FT4 measurements and a suppressed TSH level is the usual finding, some patients have nodules specifically secreting T3 and the FT3 levels will be elevated with normal or even low FT4 levels.

HYPOTHYROID GOITRE

Patients with developing Hashimoto's thyroiditis will usually develop a goitre before the biochemical changes occur. Indeed, in a small percentage of patients, there may be a brief period of thyroid overactivity or 'Hashitoxicosis' before the classical features of hypothyroidism develop. Elevation of the autoantibodies to thyroid peroxidase (TPO) and thyroglobulin are diagnostic of this condition but antibody elevation and goitrous change may precede the development of thyrotoxicosis by many years. These patients require regular biochemical review and thyroxine replacement commenced when the blood tests start to drift down.

Imaging investigations

HYPERTHYROIDISM

Whilst biochemical tests of thyroid function are the mainstay of identifying the presence of thyrotoxicosis, the underlying pathogenesis may not be diagnosed by blood tests alone. Imaging investigations will give an insight into the functionality and structure of regions of the gland.

Toxic diffuse goitre (Graves' disease)

On ultrasound the gland is moderately enlarged and in 80 percent of patients the gland is diffusely hypoechoic secondary to lymphocytic infiltration. The gland may appear normal in some patients and in others echogenic nodules are seen within the hypoechoic matrix suggesting Graves' superimposed on a pre-existing nodular goitre. A characteristic pulsatile flow pattern is seen within the gland on colour Doppler ('thyroid inferno'²²). The volume of the gland will decrease during therapy, as may the vascularity.²³

Quantitative uptake may be undertaken to measure the trapping function of the thyroid. The 20 minute uptake value for ^{99m}Tc is normally between 0.4 and 4 percent and the two hour uptake of ¹²³I iodide is 20 percent. Patients with untreated toxic diffuse goitre will have trapping values higher than the normal range. The level of uptake corresponds to the severity of the thyrotoxicosis and the level of TSH receptor antibodies.

Solitary toxic nodule

Clinical examination of the thyroid will frequently determine the presence of nodules within the thyroid. However, the presence of palpable nodule(s) in a thyrotoxic patient does not confirm a diagnosis of toxic nodular goitre as Graves' disease may occur in a multinodular goitre and Graves' disease in an asymmetrical thyroid may be mistaken clinically for a unilateral toxic nodule. Since the management of Graves' thyrotoxicosis and toxic nodular disease is different, with Graves' patients usually being offered a prolonged trial of antithyroid medication, the correct diagnosis is essential to ensure optimal management. Similarly, small multinodular goitres with toxic nodules may be difficult to palpate and a misdiagnosis of Graves' disease may be made. Imaging therefore contributes to the diagnosis of the hyperthyroid patient, and ultrasound is used to confirm the presence of a solitary nodule and ensure that appropriate management is instigated.

If a discrete nodule is identified, the ^{99m}Tc or ¹²³I thyroid scan will assess the functionality.^{24, 25} The probability of carcinoma in solitary nonfunctioning solid nodules varies from 10 to 25 percent in reported series and FNAC should be performed if such a nodule is demonstrated. The probability of cancer in a single nodule of a multinodular goitre is variably reported as 1–3 percent,²⁶ or up to 6 percent in other series.²⁷

Thyroiditis

If the patient presents with painful swelling of the thyroid or if there is any history of iodine administration, an isotope scan should be performed as soon as possible. In subacute viral thyroiditis (De Quervain's), the classical scan pattern of low or absent uptake with biochemical evidence of thyrotoxicosis is diagnostic. The uptake will normalize within four to six weeks after the onset of the illness. With iodine-induced thyrotoxicosis, the low uptake pattern on the scan may persist for many months.

The gland is moderately enlarged on ultrasound with geographical hypoechoic areas that are hypervascular. There may be associated lymphadenopathy.²⁸

Hypothyroidism

Hypothyroidism may present with the clinical symptoms of an underactive thyroid or be discovered during investigation for goitre. The swelling of the thyroid

during the early phases of Hashimoto's thyroiditis may precede the onset of classical symptoms of hypothyroidism and imaging may be of value in assessing the nature of the goitre.

The radionuclide scan pattern in Hashimoto's thyroiditis ranges from a diffuse pattern of uptake through to discrete nodular change.²⁹ In the early stages of the disorder the uptake of radioactive tracer is increased as the TSH level rises. As the gland fails functionally, the uptake value falls until eventually there is no uptake and no visualization of the thyroid on a radionuclide scan.

On ultrasound in the subacute phase, the gland is moderately enlarged and hypoechoic and returns to normal after treatment. Occasionally there are hypoechoic areas with echogenic hypervascular septa similar to those seen in Graves' disease. In the chronic phase the thyroid is small or atrophic and hypoechoic with no hypervascularity.

On CT the appearances are nonspecific with variable diffuse enlargement of the thyroid. On T2 weighted MRI, the gland may show increased signal intensity with peripheral lower-intensity bands, which probably represent fibrosis. Rarely, lymphoma may develop in the thyroid gland of a patient with Hashimoto's thyroiditis and present as a rapidly increasing swelling of the thyroid in a patient with known hypothyroidism and the development of lymphadenopathy. A ⁶⁷Ga citrate scan will identify increased uptake in the developing lymphoma of the thyroid. On ultrasound there are diffuse or focal areas of hypoechogenicity within the enlarged gland with associated lymphadenopathy. Lymphoma is of low attenuation on both unenhanced and enhanced CT scans and hypointense on T1 and T2 weighted MR images. The diagnosis can be confirmed on FNAC. Since these tumours are frequently radiosensitive, accurate diagnosis will spare the patient unnecessary surgery.

CONCLUSION

Whilst the diagnosis of thyroid disease is highly dependent on adequate history taking and clinical examination, biochemical and imaging investigations contribute significantly to the accuracy of the diagnosis and in management planning and patient monitoring.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words hyperthyroidism, thyrotoxicosis, Graves' disease, multinodular goitre, toxic adenoma, nodular thyroid disease, subclinical hyperthyroidism, thyroiditis, hypothyroidism, Hashimoto's thyroiditis, subclinical hypothyroidism. The emphasis is on pathogenesis, diagnosis and treatment.

THYROTOXICOSIS

Epidemiology

Thyrotoxicosis results from an excess of the thyroid hormones, thyroxine (T4) and/or triiodothyronine (T3). It is a common condition occurring eight to ten times more frequently in women than in men in the UK. Its prevalence is approximately 2 percent of the female UK population with an annual incidence of 2 per 1000 women.¹ Primary thyrotoxicosis results from disease of the thyroid itself; secondary thyrotoxicosis results from abnormalities in the anterior pituitary gland, the site of thyroid stimulating hormone (TSH) production. Primary thyrotoxicosis is by far the most common, the majority of cases reflecting either Graves' disease or a 'toxic' nodule occurring singly or as part of a multinodular goitre.

Although often used interchangeably, the terms hyperthyroidism and thyrotoxicosis are not identical.

Hyperthyroidism should be used when hyperfunction of the thyroid gland leads to thyrotoxicosis. **Thyrotoxicosis** is the resulting clinical, physiological and biochemical picture resulting from thyroid hormone excess which may result from a variety of causes. The causes of hyperthyroidism are outlined in Table 28.1.

Clinical manifestations of thyroid hormone excess

SYMPTOMS

Patients with florid thyrotoxicosis have an easily recognizable constellation of symptoms and signs, many of which are attributable to sympathetic overactivity. [**/*] They will complain of anxiety, poor concentration and irritability. There may be insomnia despite extreme fatigue. Appetite is increased yet weight may fall as a result of the increase in basal metabolic rate.

Table 28.1 The causes of hyperthyroidism.

Associated with hyperthyroidism	Not associated with hyperthyroidism
Autoimmune conditions	Thyroid inflammation
Graves' disease	Post-partum thyroiditis
Hashitoxicosis	De Quervain's (subacute) thyroiditis
Autonomous nodules	Drug-induced thyroiditis (amiodarone)
Toxic solitary nodule	Exogenous thyroid hormone excess
Toxic multinodular goitre	Overtreatment with thyroxine
Well differentiated thyroid cancer (very rare)	Thyrotoxicosis factitia (use of thyroxine in nonthyroid disease)
Pituitary conditions	Endogenous thyroid hormone excess
TSH-oma	Metastatic thyroid carcinoma
Other conditions	Struma ovarii (teratoma containing functional thyroid tissue)
Trophoblastic tumours (produce HCG with thyrotrophic activity)	

Stool frequency is increased yet frank diarrhoea is rare. Heat intolerance and increased perspiration are common complaints, and in women oligo- or amenorrhoea may occur.

In those with modestly elevated circulating thyroid hormones, or in the elderly patient, the symptoms are more subtle. Cardiovascular symptoms may predominate in the elderly, with palpitations, dyspnoea and peripheral oedema occurring commonly. Weight loss in conjunction with depression and agitation can occur, termed 'apathetic hyperthyroidism'.²

SIGNS

The clinical features and signs of thyrotoxicosis are summarized in **Table 28.2**. Patients may be agitated and have rapid speech and have warm, moist skin and palmar erythema. The hair may be thin and fine. The eyes may appear staring due to lid retraction and there may be lid lag, due again to sympathetic overactivity. Cardiovascular examination reveals sinus tachycardia or atrial fibrillation and in severe cases there will be signs of cardiac failure. Neurological examination may reveal a fine tremor of the outstretched hands, hyperreflexia and a proximal myopathy. There may be a goitre, the nature of which can give clues as to the aetiology of the thyrotoxicosis.

There may be a single palpable nodule in patients with an autonomously functioning adenoma or a nodular goitre in those with toxic multinodular goitre, and there may be a smooth goitre in Graves' disease (see under Graves' disease). The absence of goitre raises the possibility of exogenous thyroid hormone ingestion or struma ovarii. The thyroid is impalpable in a significant proportion (approximately 30 percent) of those with Graves' disease and toxic nodular hyperthyroidism.

Occasionally, the severity of symptoms and signs of thyroid hormone excess supports the diagnosis of 'thyroid storm', which is a medical emergency.

Table 28.2 Clinical features and signs of thyrotoxicosis.

Clinical features	Patient complaints
Sinus tachycardia, atrial fibrillation	Anxiety, agitation, irritability
Fine tremor of outstretched hands	Fast or irregular heart beat
Warm moist skin, palmar erythema	Fatigue, weakness and breathlessness
Onycholysis	Heat intolerance and increased sweating
Hair loss	Weight loss despite increased appetite
Proximal myopathy, muscle wasting	Increased frequency of defaecation
High output congestive cardiac failure	Irregular or absent periods.
Thyroid bruit	Swollen legs
	Hair loss and brittle nails

ATRIAL FIBRILLATION AND THYROTOXICOSIS

New onset atrial fibrillation or worsening heart failure may represent the development of hyperthyroidism, and atrial fibrillation complicates thyrotoxicosis in approximately 15 percent of cases. Its incidence rises with age, thus it will appear more prevalent in the elderly in whom cardiac failure or cerebral emboli may be precipitated.

Investigation of suspected thyrotoxicosis

A history and examination suggestive of thyroid overactivity should be investigated prior to initiation of treatment or further investigation. Laboratory investigations in suspected thyrotoxicosis are listed in **Table 28.3**. The single most important test is the measurement of serum TSH. If the TSH is within the normal range then a

Table 28.3 Laboratory investigations in suspected thyrotoxicosis.

Laboratory test	Findings	Comment
Thyroid function tests	Elevated free T4 and/or free T3	
Hormonal assay	Suppressed TSH	Unless TSH-oma/T3 resistance
Immunology	Positive thyroid autoantibodies	Typical of Graves' disease
Biochemistry	Elevated alkaline phosphatase	Elevated calcium
Haematology	Normochromic normocytic anaemia	Long-standing cases
Raised ESR	Subacute thyroiditis	

diagnosis of hyperthyroidism can be ruled out. The exceptions to this rule are rare pituitary causes of thyrotoxicosis such as TSH-oma or syndromes of thyroid hormone resistance. In these cases there may be a modest rise in TSH accompanied by a rise in T3 and T4.

A low TSH is not specific for thyrotoxicosis, and 'nonthyroidal' illness or treatment with a variety of drugs may lower the TSH below the normal range although it is still usually detectable in these circumstances. For these reasons it is preferable to measure the TSH in conjunction with serum T4 and, in specific cases, T3 as well.

In most cases of hyperthyroidism the typical picture is of undetectable serum TSH with elevated serum concentrations of T4 and T3. A low TSH and normal T4 should prompt T3 measurement as 10 percent of cases of thyrotoxicosis are so-called 'T3 toxicosis'. This is most commonly seen in mild cases of toxic nodular hyperthyroidism (either a single autonomous nodule or a multinodular goitre) or early in relapse of Graves' disease.

Specific patterns of thyroid function tests (TFT) are shown in Table 28.4.

THE ROLE OF SCINTIGRAPHY IN THE INVESTIGATION OF THYROTOXICOSIS

Although the biochemical diagnosis of thyrotoxicosis is easy to make, the aetiology of the underlying disease may be less clear. In most cases of thyrotoxicosis, a thorough history, examination and laboratory tests will be sufficient to make the diagnosis. In some cases where the aetiology of thyroid hyperfunction is unclear, diagnosis can be aided by the use of scintigraphy (see Chapter 27, The thyroid gland: function tests and imaging). This imaging modality can provide detail on overall thyroid size and

can be used to differentiate between 'hot' and 'cold' areas of increased and decreased function respectively. There are specific scintigraphic appearances associated with different conditions (Figure 28.1 and Table 28.5).

Graves' disease

In iodine-replete parts of the world, the disease known in Europe and the USA as Graves' disease is the most common cause of thyrotoxicosis (Figure 28.2). First described in 1835, Graves' disease is a syndrome consisting of hyperthyroidism, moderate goitre, ophthalmopathy and dermopathy. In many patients, hyperthyroidism and goitre are the only features. Signs specific to Graves' disease include:

- diffuse goitre;
- thyroid acropachy (see below);
- ophthalmopathy;
- pretibial myxoedema.

It is more common in women than men in a ratio of over 5:1. Men are often affected later and the disease may be more severe. Its peak incidence is in the twenties and thirties, but it can occur at any age, although is uncommon before puberty. Graves' disease is more common in smokers (whose risk of the disease is almost

Table 28.5 Scintigraphic appearances associated with thyroid disease.

Condition	Scintigraphic appearances
Graves' disease	Increased uptake, homogeneous pattern Overall increase in gland size
De Quervain's (subacute) thyroiditis	Low or absent uptake
Thyrotoxicosis factitia	Low uptake
Solitary toxic nodule (solitary adenoma)	Gland may be of normal size Solitary area of high uptake Uptake in surrounding gland may be suppressed
Toxic nodular goitre	Gland may be enlarged overall Patchy areas of high uptake

Table 28.4 Specific patterns of thyroid function tests.

TSH	T4	T3	Diagnosis
Suppressed	++	++	Primary hyperthyroidism
Suppressed	N	+	T3 toxicosis
Suppressed/low +/N	N	N	Subclinical hyperthyroidism
	+	+	TSH-oma
N	+	Low	Amiodarone effect without overt thyroid dysfunction

doubled) and smoking is an even stronger risk factor for the development of thyroid eye disease.

PATHOGENESIS

Graves' disease is an autoimmune condition and the hyperthyroidism is mediated by autoantibodies to the TSH receptor in thyroid tissue (TSHR-Ab). These bind to

the extracellular domain of the TSH receptor causing activation. This stimulates thyroid hormone synthesis and secretion. Increased expression of growth factors such as fibroblast growth factor (FGF) contributes to enlargement of the gland resulting in a diffuse swelling. TSHR-Ab are IgG and are thought to be oligoclonal, unlike thyroid microsomal and thyroglobulin antibodies which are polyclonal. TSHR-Ab are not measured routinely in

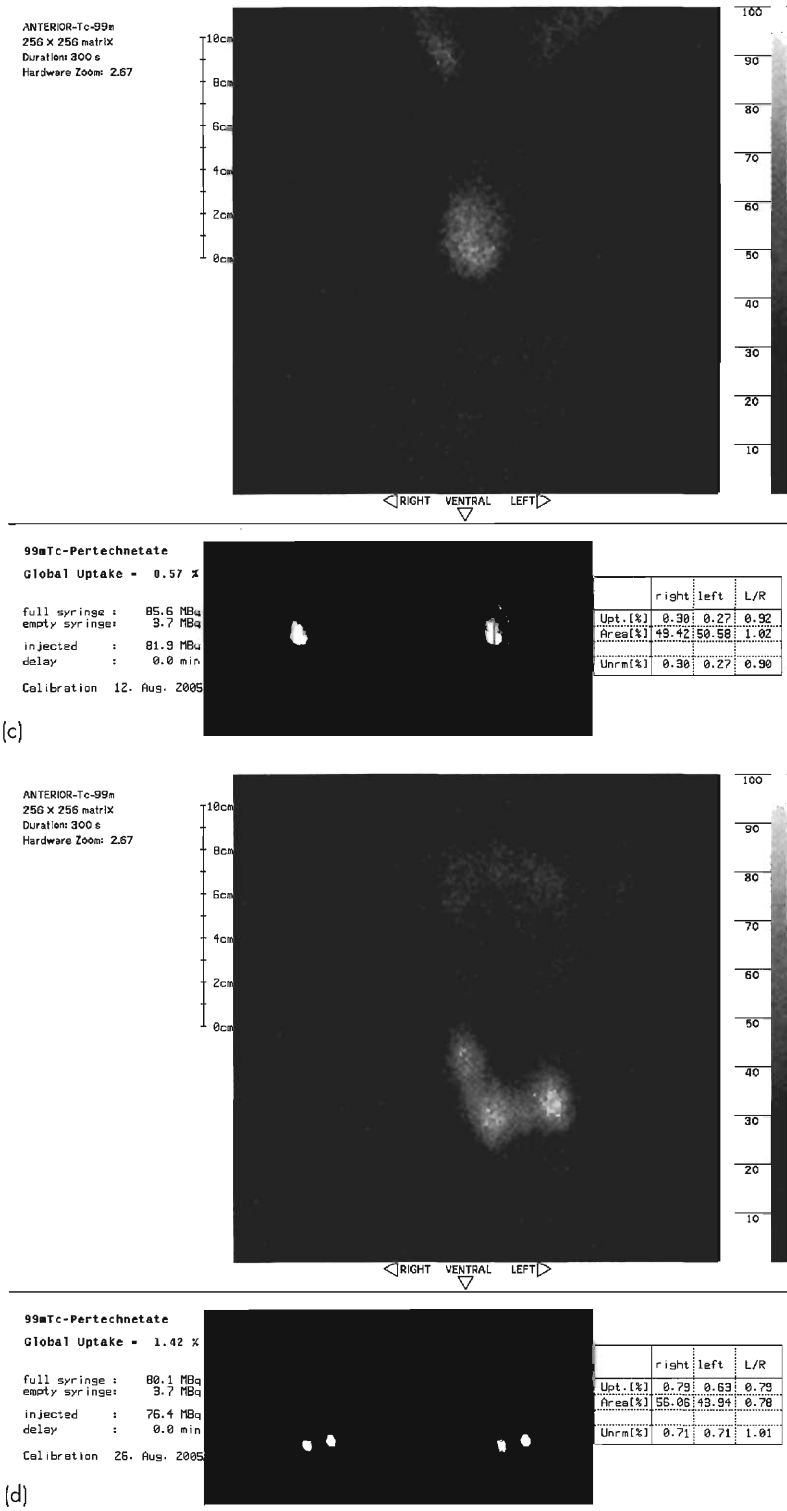

Figure 28.1 Scintigraphic appearances: (c) dominant hot nodule; (d) multinodular goitre (continued).

clinical practice as their prevalence varies between different assay systems and their presence or absence does not alter management of the individual (Figure 28.2).

Graves' disease tends to run in families, and a high concordance rate in monozygotic twins suggests a genetic contribution to the aetiology. The genetics of Graves' disease is complex with some genes conferring

susceptibility, and others protection.³ It is likely that Graves' is a polygenic disease occurring as a result of the interaction of several genetic loci in association with environmental factors, for example smoking has been suggested to increase risk. Graves' disease may be associated with other diseases mediated by the immune system.

Figure 28.3 Vitiligo in hands of patient with Graves' disease.

In Caucasians, this is especially the HLA-DR3, B8 and CTLA-4 haplotypes. Associated conditions include type 1 diabetes, vitiligo (**Figure 28.3**), coeliac disease, pernicious anaemia and Addison's disease.

CLINICAL MANIFESTATIONS AND NATURAL HISTORY OF GRAVES' DISEASE

Although Graves disease can occur rapidly over a few weeks, in most the onset is gradual and insidious. Patients exhibit many of the clinical features discussed above but in addition may have extrathyroidal manifestations such as ophthalmopathy (with exophthalmos and conjunctival oedema) and, rarely, dermatopathy and acropachy.

A diffuse goitre is present in the majority of cases but its absence does not rule out Graves' disease, as the

thyroid may be of normal size in around 3 percent. The goitre is usually symmetrical, there may be an **overlying palpable thrill** and a **bruit** may often be heard. The thrill and bruit result from the increased blood flow to the thyroid.

Graves' disease is **usually treated with antithyroid medication in the first instance**. Whilst adequate therapy is given the disease may be quiescent but may return if compliance diminishes or dosage is inappropriately reduced. **As with many autoimmune conditions, Graves' disease is sometimes self-limiting and around 30 percent of patients experience lasting remission after treatment.**

THYROID AUTOANTIBODIES

Three thyroid autoantibodies may be measured in clinical practice, those against thyroid peroxidase (TPO), thyroglobulin and the TSH-receptor. In a study of the prevalence and usefulness of thyroid autoantibodies, TPO antibodies were positive in 90 percent of cases of Graves' disease, thyroglobulin antibodies in 49 percent, whilst TSHR-Abs were found only in 45 percent.⁴ Thyroid peroxidase antibodies are thus the most commonly measured antibodies in clinical practice.

EXTRA THYROIDAL MANIFESTATIONS OF GRAVES' DISEASE

Dermopathy

This **occurs in approximately 5 percent** of patients with Graves' disease, almost always accompanied by severe eye disease. Usually occurring **over the skin of the shins and known as pretibial myxoedema**, it may affect other areas of the body. The **skin appears raised, oedematous, nodular and discoloured with a pink or brownish tinge** (**Figure 28.4**).

The **oedema is nonpitting and usually painless but may itch**. It is caused by a build-up of glycosaminoglycans along with a florid lymphocytic infiltrate. Although not usually treated, if severe, fluorinated steroids may be used topically with occlusive dressings.

Acropachy

This is **very rare and presents as clubbing of the fingers** with subperiosteal new bone formation seen on plain radiograph. Again, thought to arise from glycosaminoglycan accumulation, it occurs in conjunction with ophthalmopathy or dermatopathy. **There is no treatment.**

Thyroid eye disease

Many patients with Graves' disease have involvement of the eyes. Clinically detectable disease **is present in around 30 percent**, while imaging such as MRI will provide evidence of eye involvement in a much larger proportion. In the majority of cases eye disease is mild; however in some cases it may be severe (**Figure 28.5**). **Patients who smoke are**

Figure 28.4 Pretibial myxoedema.

Figure 28.5 Thyroid eye disease: MRI orbits, showing enlarged extraocular muscles. With kind permission from Mr J Uddin, Moorfields Hospital, London, UK.

more likely to suffer eye disease of greater severity than nonsmokers and hypothyroidism may exacerbate it. In approximately three-quarters of cases, Graves' disease will develop either a year before or a year after eye problems begin, but on occasions this period may be longer. In these cases one may falsely conclude that one is looking at a case of 'euthyroid Graves' ophthalmopathy'. At diagnosis, 5 percent of patients are hypothyroid and 5 percent are euthyroid. The ophthalmopathy is characterized by

swelling of the extraocular muscles, proliferation of periorbital fat and late fibrosis leading to muscle tethering. The lesions develop due to an accumulation of glycosaminoglycans and a lymphocytic infiltration of the orbital and retro-orbital tissues.

Clinical features of ophthalmopathy

Early in the disease, patients may complain of irritation in the eyes and a feeling of a foreign body. There may be excessive watering, especially in the wind. As the disease progresses, there may be a change in physical appearance with periorbital oedema and/or a staring expression caused by exophthalmos and/or eyelid retraction. Eyelid retraction may give the false impression of proptosis, though both most often coexist. This may be bi- or unilateral and patients may complain of a feeling of pressure behind the eyes. Even in apparent unilateral cases, one will find evidence of bilateral disease, provided the right imaging techniques are used, such as MRI (Figure 28.5) or CT scanning. In the worst cases the eyes may not close fully at night leading to corneal ulceration and scarring. There may be apparent nerve palsies due to infiltration of the extraocular muscles with fat and fibrotic changes.

Signs of thyroid eye disease

Signs of thyroid eye disease include:

- conjunctival oedema;
- periorbital oedema;
- proptosis greater than 22 mm;
- corneal ulceration;
- decreased colour vision;
- conjunctival injection;
- lid retraction and lid lag;
- squint and eye movement problems;
- papilloedema;
- decreasing visual acuity.

Decreasing visual acuity and a loss of colour vision are ominous signs and may be caused by pressure on the optic nerve by the swollen extraocular muscles, or – less commonly – sheer stretch of the optic nerve. Urgent treatment is needed if permanent visual loss is to be avoided; the following symptoms indicate that the patient should be referred to an ophthalmologist as a matter of urgency:

- rapid deterioration in visual acuity;
- decreased colour vision;
- squint and eye movement problems;
- visual acuity of less than 6/18;
- corneal ulceration.

The disease occurs in two phases: a dynamic active phase and a quiescent phase. Unfortunately, even when well-treated and quiescent, patients do not always

achieve a return in physical appearance to the premorbid state.

Treatment of thyroid eye disease

For mild disease, often no treatment is necessary. For local discomfort, artificial tears are useful, as is elevation of the head of the bed to reduce oedema. As proptosis and conjunctival oedema worsen, treatment with **parenteral or high-dose oral steroids** is required for a period of weeks. **Radiotherapy** is also a treatment option in early and active disease. Ocular nerve palsies need treatment by an experienced surgeon, as multiple operations may be necessary to align eye movements. Optic neuropathy may be treated both medically and surgically (**Figure 28.6**) with high-dose steroids, radiotherapy and **orbital decompression** having a role.⁵

Toxic multinodular goitre

EPIDEMIOLOGY AND PATHOGENESIS

Although Graves' disease is the commonest cause of thyrotoxicosis, in the elderly, nodular thyroid disease predominates. In all age groups, toxic nodular thyroid disease is more common in areas of the world where iodine is relatively deficient and, like all thyroid disease, is commoner in women than in men. The pathogenesis, aetiology and natural history of the goitre are covered in detail elsewhere, but may progress from diffuse enlargement to the development of one or more nodules. Autonomous function of one or more of these nodules results in thyrotoxicosis.

This may occur spontaneously or as a result of exposure to increased quantities of iodine (e.g. in contrast media), termed the Jod Basedow effect. Due to the long

natural history, an elderly patient presenting with a toxic multinodular goitre (MNG) may describe the presence of the goitre many years before the thyrotoxicosis develops.⁶

CLINICAL MANIFESTATIONS OF TOXIC MNG

In general, this diagnosis is observed in an older patient group than those who present with Graves' disease, and the degree of thyroid hyperfunction is typically less marked. For these reasons, the classical clinical symptoms and signs of thyrotoxicosis may not all be present. It is the cardiovascular effects that predominate, these include palpitations, atrial fibrillation and other tachyarrhythmias. In addition, patients with toxic MNG may complain of the presence of a goitre which may be longstanding. There may be dysphagia to solids and dyspnoea especially at night.

Toxic adenoma (Plummer's disease)

EPIDEMIOLOGY AND AETIOLOGY

A single toxic adenoma is a benign tumour autonomously secreting thyroid hormone. This is a rare cause of thyrotoxicosis and in the US accounts for only 2 percent of cases. A mutation in the TSH receptor gene occurs in 20–83 percent^{7, 8} of patients with a toxic adenoma. Several point mutations of this gene have been identified, mostly in the transmembrane domain (see **Figure 28.1c**). The mutations are somatic, i.e. not in the germ line, and are therefore **not inherited**. These mutations result in the TSH receptor being activated, leading to **autonomous function not under pituitary control**. For this reason, the first biochemical abnormality often seen is suppression of serum TSH with a normal circulating T4 concentration. This is termed 'subclinical hyperthyroidism' and presents a complex problem (see below under Subclinical hyperthyroidism).

CLINICAL MANIFESTATIONS

Patients with a toxic adenoma are **often younger than those with a toxic MNG**, and present in the fourth or fifth decade. There may be a history of a slowly enlarging neck mass and many will have a palpable nodule. This is not always the case, as the autonomously functioning tissue may be diffuse and in this case the thyrotoxicosis may incorrectly be attributed to Graves' disease. The level of thyroid hyperfunction is again less than is seen in Graves' disease, so the symptoms and signs may not be so florid.

As Graves' disease may be treated differently to toxic MNG or a toxic adenoma correct diagnosis is important. The presence of a high titre of microsomal antibodies is

© Hodder Arnold / Scott-Brown 7E

Figure 28.6 Patient with thyroid eye disease and optic neuropathy. (a) Pre-corrective surgery. Note the upper lid retraction, corneal injection, periorbital fat deposition and proptosis. (b) After surgical decompression. With kind permission from Mr J Uddin, Moorfields Hospital, London, UK.

more suggestive of Graves' disease, whilst scintigraphy distinguishes Graves' disease from toxic MNG and single toxic adenoma.

The treatment of thyrotoxicosis

MEDICAL TREATMENT

The initial approach to the hyperthyroid patient is to minimize symptoms (often with a beta-adrenergic blocking drug) and to reduce the synthesis of thyroid hormones. Three modalities of treatment exist: drug therapy, radioiodine treatment and surgery. These are summarized in Table 28.6. One randomized controlled trial compared thionamides, radioiodine and surgery in the treatment of hyperthyroidism and concluded that each was as effective at reducing thyroid hormone concentration in six weeks.⁹

DRUG TREATMENT

Antithyroid drugs

The thionamides – carbimazole (or its active metabolite methimazole) and propylthiouracil represent the mainstay of drug treatment of thyrotoxicosis. [***] [Grade B] These drugs block the organification and oxidation of iodide, thus blocking the synthesis of T4 and T3 early in their biosynthetic pathway. They are the most effective and rapid way of reducing circulating thyroid hormone concentration. They may be used in several ways:

- short term in the preparation for definitive treatment with radioiodine or surgery;
- medium term in the hope of inducing remission in Graves' disease;

- long term for control of clinical and biochemical thyroid hormone excess.

Dose regimen

Carbimazole is usually given in a starting dose of 20–30 mg per day in a single dose. Propylthiouracil (PTU) is given in divided doses and 200 mg of PTU is approximately equivalent to 20 mg carbimazole.

Side effects

Side effects can occur with both carbimazole and PTU. The most common side effect is a pruritic rash, which can usually be managed conservatively. Occasionally, the rash necessitates a change from one drug to the other and cross reactivity in this context is typically not a problem. Other relatively minor side effects include fever, urticaria and arthralgia. Mild side effects occur in 1–5 percent of patients. More serious side effects are rare and include development of an antineutrophil cytoplasmic antibody-associated vasculitis (typically associated with PTU) and hepatitis (induced more often by carbimazole than PTU).

The most serious side effect, agranulocytosis, occurs in less than 1 in 1000 patients. Agranulocytosis typically occurs in the first few weeks of treatment and is more common in those taking high doses. For this reason it is essential that all patients are warned (preferably in writing) of the risk of agranulocytosis and that clear instructions are given to present urgently for a full blood count if they develop a fever or sore throat. The agranulocytosis is usually transient and resolves after thionamide withdrawal. Agranulocytosis, along with hepatitis and vasculitis, is an absolute contraindication to the further use of thionamides.

Drug treatment of Graves' disease

Thionamides are used in Graves' disease due to their inhibitory effect on thyroid hormone synthesis and because of a questionable immunomodulatory effect.¹⁰ If an established diagnosis of Graves' disease has been made, then the patient may be offered a full course of thionamide therapy in the hope of inducing remission. Two randomized controlled trials have attempted to define the optimal duration of treatment and concur that treatment should be offered for a period of 12–18 months^{11,12} as shorter courses are associated with higher rates of relapse. Treatment duration is agreed with the patient at the outset, but at any point medication may be stopped if definitive therapy is preferred. Drug doses are titrated according to the serum concentration of T4. This should be measured regularly, ideally every four to six weeks initially, then 8–12 weekly once control is achieved. Serum TSH may remain suppressed in the medium to long term in patients with Graves' disease. Most patients require a maintenance dose of 5–10 mg carbimazole and

Table 28.6 Advantages/disadvantages of treatment modalities for thyrotoxicosis.

Treatment	Advantages	Disadvantages
Thionamides	Rapid symptom relief	Risk of severe side effects
	Inexpensive drugs	Frequent clinic visits
	Chance of remission	Common mild side effects
	No exposure to radioactivity	Long course of treatment
Radioiodine	Definitive treatment	High chance of relapse
	Outpatient procedure	Risk of hypothyroidism
		Radiation protection measures
Surgery		Radiation thyroiditis
	Definitive treatment	Inpatient procedure
	Histological diagnosis	Risk of surgery
		Permanent hypothyroidism
		Risk of hypocalcaemia

50–100 mg PTU. Larger requirements are suggestive of poor compliance.

Efficacy and relapse

Remission rates with this regimen are less than 50 percent,⁹ although may be slightly higher in the elderly. Relapse usually occurs within three to six months of thionamide withdrawal, in which case patients should be offered definitive treatment.

Increased likelihood of remission is associated with a small goitre or one that shrinks during therapy, although age and sex appear to be the most important predictors. Remission in men is approximately 20 percent, compared to 40 percent in women, and 33 percent for those less than 40 years of age, compared to 48 percent for those over 40. The ability to accurately predict who will enter remission would be of great benefit but at present is not possible. Once remission has been achieved, cure is likely if the patient remains euthyroid for six months, although a slowly increasing proportion relapses with length of time of follow-up. Relapse may occur after several years; poor prognostic factors for relapse of medically treated Graves' disease include:

- male sex;
- large goitre;
- severe biochemical disease at diagnosis;
- high T3 to T4 ratio;
- young age.¹³

Thionamides alone or 'block and replace'

Although most clinicians use thionamides alone to treat Graves' disease, some prefer the 'block and replace' regimen that uses thionamides to block endogenous thyroid hormone production completely, which is then replaced with thyroxine. Advocates believe this latter approach requires less monitoring and leads to better compliance.

There is no substantial evidence that the block and replace approach has any advantages in terms of remission of Graves' disease. There is clear evidence for increased side effects, some serious, probably related to the higher doses of thionamides required.¹⁴ This regimen is also contraindicated in pregnancy because thionamides cross the placenta more easily than T4, leading to the potential for foetal goitre and hypothyroidism.

Drug treatment of toxic MNG and toxic adenoma

Thionamides do not induce remission or cure of thyrotoxicosis which is due to nodular disease. They may be used in the short term to induce euthyroidism, prior to proceeding to definitive treatment. As the thyrotoxicosis is usually biochemically less severe than Graves' disease, the starting dose of thionamides may be smaller, and if surgery or radioiodine is not appropriate, thionamides can be continued indefinitely.

Adjuncts to antithyroid drugs

Beta-adrenergic blockers

Beta-adrenergic blockers are useful adjuncts to thionamides in the treatment of thyroid hormone excess. They act promptly to reduce the symptoms, such as tremor, palpitations and tachycardia, but should be used cautiously in the elderly where heart failure may be present. Propranolol given three times a day or longer acting beta blockers, such as nadolol and atenolol, are the most widely used.

Anticoagulants

In patients who develop atrial fibrillation, anticoagulation with warfarin should be considered due to the risk of embolic complications. There have been no controlled trials of the use of anticoagulants in thyrotoxic atrial fibrillation (AF) but overwhelming evidence of their efficacy in other settings argues in favour of their use unless clear contraindications exist. Approximately half of those with thyrotoxic AF will revert spontaneously to sinus rhythm; this typically occurs within three months of initiation of antithyroid therapy. For those who remain in AF, joint cardiological management involving specific therapy to restore sinus rhythm may be considered when the patient is euthyroid. Chemical or electrical cardioversion is more likely to restore sinus rhythm in those whose AF is of short duration and in those who have no underlying heart disease.

Radioiodine (iodine-131)

Administration and side effects

Radioiodine generally represents the treatment of choice for hyperthyroidism, either as a first line in Graves' disease, toxic multinodular goitre or toxic adenoma, or as a second line in patients where treatment has failed in those initially treated with a course of thionamides for Graves' disease. [***] [Grade B] Radioiodine is administered orally as sodium I¹³¹ in capsule form, and may be given in the outpatient department. It is incorporated into thyroid tissue and the beta emissions result in lasting thyroid tissue damage. There is a lag effect with the maximum thyroid ablation occurring over six weeks to four months.

Efficacy and dosage

Radioiodine is the most popular first-line treatment for hyperthyroidism in the USA, with approximately 70 percent of physicians preferring radioiodine to treat Graves' disease.¹⁵ Traditionally less popular in the UK, most large thyroid centres now also advocate radioiodine as the treatment of choice for Graves' disease. Depending on dose, 50–70 percent of patients achieve euthyroidism and shrinkage of goitre around two months after therapy.

The Royal College of Physicians of London recommended that the dose used should be enough to achieve euthyroidism with an acceptable risk of the subsequent

development of hypothyroidism.¹⁶ Empirical fixed doses of between 400 and 600 MBq are used to achieve these aims. Studies have attempted to define the optimal radioiodine dose for an individual patient in the hope of avoiding iatrogenic hypothyroidism. Factors such as thyroid size (judged clinically or by imaging), isotope uptake or turnover have been studied. A review of the current literature suggests that measurement of gland size and radioiodine uptake/turnover do not allow effective dose titration. In addition (and in conflict with older literature), it is clear that the dose of radioiodine required to cure toxic nodular hyperthyroidism is not different from that required in Graves' disease in the majority of cases. In iodine-replete countries such as the USA and the UK, doses of between 400 and 600 MBq are commonly used. Some centres give larger doses to men and those with large goitres in whom it is suggested that relative radioiodine resistance may be found.

Larger doses may be preferable in the elderly, especially in those with concomitant heart disease, to be certain of rapid resolution of hyperthyroidism.

Safety

Many patients are concerned about the concept of radiation treatment and perceive that there may be an increased risk of subsequent cancer. Radioiodine has been used for many years, with well-established efficacy. In terms of cancer, long-term safety has been well demonstrated.¹⁷

In children and adolescents, the thyroid appears to be more sensitive to the effects of radiation and most paediatricians would avoid radioiodine in these cases. National radiation protection policies exist and include measures to avoid contamination of the home or work place with I¹³¹, including avoidance of close contact with small children, avoiding sharing utensils and sleeping alone.

Contraindications to radioiodine

Pregnancy is an absolute contraindication to the use of radioiodine due to the risk of ablating foetal thyroid tissue and resulting cretinism. A pregnancy test is necessary before administration of radioiodine and pregnancy should be avoided for four months after treatment to allow for resolution of the effects of transient gonadal radiation. Inadvertent pregnancies may be allowed to proceed to term, albeit with close monitoring. With exposure early in pregnancy there is a theoretical potential late cancer risk due to foetal irradiation, and exposure after 14 weeks may result in thyroid ablation, however, there is little evidence to suggest that birth defects are increased in this group. Radioiodine is also contraindicated in women who are lactating, in young children due to the risk of developing subsequent thyroid carcinoma, and in those who are unable to understand or comply with local radiation protection measures. This latter category excludes the elderly mentally infirm and those who are incontinent of urine.

Pretreatment with antithyroid medication

In those who are young and tolerating hyperthyroidism well, or those with modest elevation of thyroid hormones, radioiodine may be used as a first-line agent, perhaps with the concomitant use of beta-adrenergic blockers for symptom control. In the majority of cases, pretreatment with antithyroid drugs is preferred to make the patient as close to euthyroidism as possible before radioiodine is given. This is because it may take three to four months for radioiodine to induce euthyroidism whereas thionamides act much more quickly.

There may also be a temporary exacerbation of hyperthyroidism as the radiation damage causes follicular destruction and 'dumping' of preformed thyroid hormone into the circulation. Depleting the thyroid hormone stores with thionamides is advisable in the elderly or those with cardiac disease, which may be exacerbated by worsening hyperthyroidism. If pretreatment is necessary, then carbimazole may be preferable to PTU, as there is some evidence to suggest that there is a higher failure rate of a given dose of radioiodine when PTU is used.

Whichever thionamide used must be discontinued shortly before radioiodine administration to allow maximum uptake into the gland. Success rates fall from over 90 percent to under 50 percent if the drug is continued at the time of radioiodine administration.

Most clinicians advise discontinuing thionamides five days to a week before radioiodine is given and many recommend that the drug is restarted afterwards, especially in those with severe disease or who tolerate hyperthyroidism poorly. It may then be tailed off according to measurements of serum T4 concentration.

Side effects

Some patients notice a sore throat or neck tenderness reflecting a radiation thyroiditis, which is thought to occur in around 1 percent of cases. These symptoms are usually mild and transient. As a result of thyroid ablation, the main side effect of radioiodine treatment is hypothyroidism, although the percentage of patients who become so during the first year varies according to the dose of radioiodine used. After the first year, the annual incidence is around 3 percent and seems dose independent.

Follow-up

+TFT

In the short term, clinical assessment of the patient should be carried out every four to six weeks. In addition to serum TSH, serum T4 concentration should be measured. Measurement of TSH concentration alone may be misleading as it may be suppressed for many months after treatment and does not necessarily imply that relapse is imminent, especially if the patient is clinically euthyroid and the serum T4 concentration is normal. If biochemical hyperthyroidism persists after a six-month period, it is likely that a second (and rarely a third) dose of radioiodine will be necessary, eventual hypothyroidism in these cases

being common. Those treated with low-dose radioiodine, males, those with severe hyperthyroidism, and those with a medium to large goitre are less likely to be cured after a single dose of I^{131} .¹⁸

All patients who have received radioiodine require long-term biochemical follow-up. Effectively achieved with a computerized recall system, this is essential as the incidence of hypothyroidism is significant many years after treatment with radioiodine and, eventually, up to 90 percent may become hypothyroid. Annual measurement of serum TSH is appropriate.

Radioiodine and Graves' disease

Radioiodine is increasingly regarded as the treatment of choice in Graves' disease. In certain groups of patients, such as young women or those with mild disease, a course of thionamide therapy may be appropriate in an attempt to induce remission.

In general, radioiodine may be considered as first line, especially in those whom antithyroid medication is unlikely to result in a cure, for example in young men.

Some attempt to achieve euthyroidism with low-dose radioiodine but there are problems with this approach. Firstly, Graves' may recur in the thyroid remnant resulting in recurrent hyperthyroidism. In addition, uncontrolled hyperthyroidism results in a permanent reduction in bone density, and subclinical hyperthyroidism is a risk factor for AF. As the primary aim is to cure the hyperthyroidism, many physicians give radioiodine in a dose large enough to attain euthyroidism in the majority and to avoid recurrence. A dosage of 4–600 MBq results in euthyroidism in 90 percent of cases but at the expense of around 70 percent hypothyroidism over 20 years.

Radioiodine and ophthalmopathy

Evidence suggests that radioiodine may worsen moderate to severe ophthalmopathy. Studies have shown that the administration of corticosteroids may ameliorate or even prevent the development of ophthalmopathy. Most physicians delay administration of radioiodine until moderate or severe eye disease has been stable for 12 months. Those with mild eye disease are given radioiodine alongside a course of steroid prophylaxis.¹⁹

Radioiodine and nodular thyroid disease

Radioiodine may be used as the definitive treatment of toxic nodular thyroid disease. It can be used as first-line treatment in those who have mild biochemical hyperthyroidism and who tolerate it well. In the elderly, pretreatment with a thionamide is necessary to rapidly relieve hyperthyroidism prior to administration of radioiodine, or following medical Tx.

Radioiodine is effective in achieving euthyroidism and, in those with autonomously functioning nodules, hypothyroidism is less common. The autonomously functioning nodule causes TSH suppression, which, in turn, suppresses surrounding thyroid tissue;²⁰ radioiodine is then preferentially taken up into the nodule with sparing of the rest of the gland. Radioiodine may also cause shrinking of nodular goitres, with a reduction in thyroid size of 45 percent after two years.

Although around 90 percent are cured, those with large goitres or with severe hyperthyroidism may not achieve a cure with a single dose of radioiodine and a subsequent dose may be necessary after six months treatment with antithyroid medication.²¹

SURGERY

Indications for surgery

Although most experts agree that surgery has little part to play in the routine management of thyrotoxicosis, there are instances where partial or subtotal thyroidectomy is a safe and effective treatment for thyroid overactivity. [***] [Grade B] Table 28.7 lists the indications for thyroid surgery.

Preparation for surgery

Thorough preparation is required to avoid thyroid storm postoperatively, as well as other significant, often cardiovascular complications. 'Thyroid storm' is due to the liberation of preformed thyroid hormone during surgery (see Table 28.8). Antithyroid drugs are routinely used prior to surgery to restore euthyroidism and, in addition, propranolol or another beta-adrenergic blocker

Table 28.7 Indications for thyroid surgery.

Indication	Comment
Patient fear/rejection of radioiodine	
Additional nonfunctioning nodule	If carcinoma cannot be excluded
Cosmetically unacceptable goitre	Slow shrinkage occurs with radioiodine
Severe ophthalmopathy and uncontrolled disease	No worsening of ophthalmopathy with surgery
Radiation protection rules cannot be followed	Mothers of infants, incontinent, mentally infirm
Local compressive symptoms (toxic MNG)	Radioiodine will also cause slow shrinkage
Pregnant women with severe side effects to thionamides	
Pregnant women with severe uncontrolled disease	Surgery performed in second trimester
Occasionally for amiodarone-induced thyrotoxicosis	If thionamides/steroids ineffective

Table 28.8 Features and management of extremes of thyroid dysfunction, myxoedema coma and thyroid storm.

Predisposing factors	Features/signs	Treatment	
		General measures	Specific measures
Myxoedema coma	<p>Occurs in elderly patients with hypothyroidism who:</p> <ul style="list-style-type: none">• have withdrawn thyroxine;• have a severe concomitant illness;• are inactive, immobile or live in unheated accommodation.	<p>Ideally HDU/ITU</p> <ul style="list-style-type: none">• Treat precipitating illness with antibiotics if necessary.• Slow rewarming (0.5°C/h).• Warm humidified oxygen or ventilation if necessary.• Monitor and treat arrhythmias.• Correct hypotension and electrolyte imbalance.	<ul style="list-style-type: none">• T4 300–500 µg via NG tube, then 50–100 µg daily.• If no improvement T3 10 µg i.v. 8 hourly or 25 µg orally.• Hydrocortisone 50–100 mg 6–8 hourly unless hypocortisolism excluded.
Thyroid storm	<p>Develops in hyperthyroid patients with acute infection who:</p> <ul style="list-style-type: none">• are post-partum;• have undergone thyroid or nonthyroid surgery;• receive iodine containing contrast agents;• withdraw antithyroid medication.	<p>Rare but life-threatening condition, significant mortality (up to 50%):</p> <ul style="list-style-type: none">• severe signs of hyperthyroidism;• fever/hyperpyrexia;• alteration in mental state;• tachycardia or tachyarrhythmias;• vomiting, diarrhoea;• multiorgan failure – cardiac failure, hepatic congestion with hyper-bilirubinaemia and jaundice, dehydration and renal failure.	<p>Best carried out in ITU</p> <ul style="list-style-type: none">• Cooling, fluid balance, antibiotics, respiratory support if necessary.• Correction of electrolyte imbalance.• Standard antiarrhythmic therapy.• Anticoagulation if in atrial fibrillation.• Chlorpromazine if agitated.

may be required if euthyroidism has not been achieved by the time of operation. In some cases, for example those unable to take antithyroid medication due to serious side effects, it is vital to prevent the release of preformed thyroid hormone. Potassium iodide may be given for three days preoperatively to decrease thyroid secretion and reduce vascularity, during this time bruits disappear and the gland will be firm.

In the past, Lugol's iodine was traditionally used in this respect but is now avoided due to the unpredictable response and its potential for exacerbation rather than improvement in thyrotoxicosis.

Complications of surgery

Complications of thyroidectomy are relatively unusual, as there is universal agreement that those who perform such surgery should be experienced and perform it frequently. The most serious complication is bleeding into the operative site with airway compromise due to haematoma. Immediate evacuation of the clot and ligation of bleeding vessels is required. Damage to the recurrent laryngeal nerve is possible during surgery and vocal cords are checked prior to surgery. Unilateral damage causing some hoarseness usually improves after a few weeks. Bilateral damage is rare, but serious, as stridor develops soon after extubation. The ensuing airway obstruction necessitates a tracheostomy.

Damage to the parathyroid glands may be transient resulting from direct insult or an interruption of blood flow to the glands. The frequency and severity of damage increases with the extent of thyroid surgery and also correlates with the incidence of postoperative hypothyroidism. Transient hypocalcaemia may be seen post-operatively and the patient may be symptomatic with signs of neuromuscular excitability such as Chvostek's sign, Trousseau's sign and carpopedal spasm. Hypocalcaemia typically occurs one to seven days post-surgery; repeated measurement of serum calcium concentration is mandatory in this period, as is close clinical monitoring of the patient for the signs outlined above. Mild hypoparathyroidism may be treated orally with calcium supplements but more severe cases will require intravenous calcium gluconate.

Other complications of thyroidectomy include wound infection and keloid formation.

Surgery and Graves' disease

In most large centres the surgical treatment of choice in Graves' disease is a total thyroidectomy. In expert hands the recurrence rate with this procedure is less than 4 percent but at the expense of hypothyroidism, such that the patients leave hospital on T4 therapy.

Surgery and nodular thyroid disease

Toxic nodular hyperthyroidism may be treated by thyroid lobectomy or excision of a single hot nodule. The adenomas are often easy to excise and there is very little

risk of either recurrence or postoperative hypothyroidism. For patients with a toxic MNG, surgery is appropriate for those with compressive symptoms, such as dysphagia and upper airway obstruction, and for those with a cosmetically unacceptable goitre. Radioiodine may cause shrinkage of the gland and may be preferable in the high-risk patient although the rate of shrinkage is relatively slow.

Best clinical practice

Investigation of thyrotoxicosis

- ✓ Measure T4, TSH and thyroid autoantibodies in suspected hyperthyroidism. T3 and ESR may be useful.
- ✓ Ultrasound and nuclear medicine scans should be reserved for specialist use.
- ✓ Hyperthyroidism due to thyroiditis is often self-limiting. Treat with nonsteroidal anti-inflammatory drugs (NSAID) + / – beta blockers.

Treatment of thyrotoxicosis

- ✓ Treat hyperthyroidism with antithyroid drugs + / – beta blockers and refer to an endocrinologist.
- ✓ Warn patients (preferably in writing) of the side effects of thionamides.
- ✓ 'Block and replace' regimes with both thyroxine and thionamides are of unproven benefit.
- ✓ Radioiodine is safe and effective but hypothyroidism may result.
- ✓ Consider radioiodine as first line for the elderly and those with cardiac dysfunction.
- ✓ Severe Graves' ophthalmopathy is an emergency – refer urgently to an ophthalmologist.
- ✓ Reserve surgery for toxic multinodular goitre with compressive symptoms, severe eye disease, severe disease in pregnancy and in those who decline radioiodine.

TRANSIENT THYROTOXICOSIS/THYROIDITIS

Transient thyrotoxicosis may occur during the acute phase of thyroiditis. [**] [Grade C] The classification of thyroiditis is confusing but may be divided into those processes in which pain and tenderness develop, and those that do not have pain as a predominant feature (Table 28.9). Generally, the former rarely result in permanent hypothyroidism, but the latter often do.

Subacute (granulomatous/De Quervain's) thyroiditis

De Quervain's, giant cell or subacute thyroiditis is an uncommon cause of transient thyrotoxicosis. The typical

Table 28.9 Classification of thyroiditis.

Associated with pain and tenderness	No association with pain and tenderness	Also known as
Hypothyroidism rare Subacute granulomatous thyroiditis (De Quervains')	Hypothyroidism often Subacute lymphocytic thyroiditis	Painless/silent thyroiditis
Infectious thyroiditis Gm+ /Gm— organisms Mycobacteria	Occurring postpartum	Post-partum thyroiditis
Radioiodine-induced thyroiditis	Drug induced Chronic lymphocytic thyroiditis Occurring post-partum Fibrous thyroiditis Amiodarone-induced thyroiditis	Lithium-induced thyroiditis Hashimoto's thyroiditis Post-partum thyroiditis Reidel's thyroiditis

patient is female and aged between 40 and 60. Presentation is with pain in the region of the thyroid, often (but not always) with swelling. This is associated with systemic symptoms such as fever, dysphagia and malaise. The pain is a striking feature, may radiate to the ear and is worse on turning the head. On examination there is often swelling of either thyroid lobe, which may be extremely painful to palpate. Signs of thyrotoxicosis may present, such as tachycardia, tremor and irritability. There may also be fever. It can take eight weeks for pain to resolve and a complete resolution is seen in six months. Laboratory tests show raised inflammatory markers, such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), and there may be a normocytic normochromic anaemia.

Thyroid scintigraphy with Tc^{99m} or $I^{125/131}$ shows a complete absence of uptake, although this can also occur with thyrotoxicosis factitia and iodine-induced hyperthyroidism. Histology is characteristic and lends the condition its name, with multinucleate giant cells surrounding a central core of colloid. Initial TFTs show thyrotoxicosis with a suppressed TSH and an elevated serum T4. This reflects destruction of the thyroid follicles by the inflammatory process and release of preformed thyroid hormone.

At 12–16 weeks there may be a hypothyroid phase during which the damaged tissue is unable to generate thyroid hormone. Most patients do not require treatment with thyroxine and most are ultimately euthyroid.²² Rarely, hypothyroidism may be permanent. Initially, thyroid autoantibodies may be positive but again this is often transient although some retain thyroid autoimmunity for life. The course of subacute thyroiditis is shown in Figure 28.7.

Treatment is supportive. Nonsteroidal antiinflammatory drugs such as aspirin and indomethacin are effective analgesics; beta-adrenergic blockers are useful if symptomatic in the thyrotoxic phase. Rarely, the severity may necessitate high-dose steroids (e.g. prednisolone 30–40 mg daily) which are extremely effective in reducing the pain

Figure 28.7 Course of subacute thyroiditis.

and swelling but must be withdrawn slowly over some months if the condition is not to recur.

The female preponderance, seasonal incidence, geographical aggregation and raised inflammatory markers have led to a hypothesis of a viral aetiology. Mumps virus, Coxsackie, influenza and adenoviruses have been implicated in the development of the disease although viral role in pathogenesis remains obscure.

Silent/painless thyroiditis

Painless thyroiditis can occur in the early stages of autoimmune thyroiditis. This may lead to mild biochemical hyperthyroidism and occasionally to symptomatic thyrotoxicosis. The thyrotoxicosis is generally mild and raised markers of inflammation are rarely found in contrast to subacute thyroiditis. The thyroid is enlarged in approximately half of the patients and is not painful. Fine needle aspirate reveals the changes

associated with Hashimoto's disease and includes extensive lymphocytic infiltrate with plasma cells rather than multinucleate giant cells. Thyroid autoantibodies are often positive.

The duration of the thyrotoxic phase is around eight weeks and symptomatic treatment with beta-adrenergic blockers may be required. There then follows a hypothyroid phase that can last over six months. In most, euthyroidism is eventually restored but permanent hypothyroidism is almost certain to develop over time.

KEY POINTS

- Thyrotoxicosis affects around 2 percent of the female population.
- Signs and symptoms are due to sympathetic overactivity.
- Most thyrotoxicosis is due to Graves' disease but nodular thyroid disease is more common in the elderly.
- Treatment aims to ease symptoms and reduce thyroid hormone synthesis.
- Antithyroid drugs may induce a remission in Graves' disease but not in nodular thyroid disease.
- Radioactive iodine is effective in treating thyrotoxicosis, often at the expense of hypothyroidism.
- Total thyroidectomy may be necessary in some cases.
- Transient thyrotoxicosis may result from thyroiditis.
- Thyrotoxicosis may complicate pregnancy, and post-partum thyroiditis is relatively common.
- Subclinical hyperthyroidism predisposes to atrial fibrillation and may contribute to osteoporosis.

SUBCLINICAL HYPERTHYROIDISM

This is essentially a biochemical diagnosis consisting of an undetectable serum TSH concentration with a normal T4 and T3 concentration. Subclinical hyperthyroidism may be exogenous as a consequence of treatment with thyroxine, or endogenous as a result of nodular thyroid disease or undetected early Graves' disease. Exogenous subclinical hyperthyroidism is by far the largest group with over 20 percent having low TSH values on at least one occasion.²³ In the USA, over 600,000 elderly patients are estimated to be overtreated with thyroxine.

Complications

Potential complications of subclinical hyperthyroidism include a loss of bone mineral density, an increase in risk of AF and cardiovascular disease.

Evidence that subclinical hyperthyroidism is a risk factor for AF is clear, indeed it has been suggested that those aged over 60 with an undetectable TSH have a three-fold increase in relative risk.²⁴ Low TSH appears to affect long-term survival, since in the elderly population an increased mortality due to cardiovascular causes can be predicted by a single low TSH measurement.²⁵ There is evidence that subclinical hyperthyroidism is associated with osteoporosis, especially in postmenopausal women,²⁶ but clear evidence for an increased risk of fracture is lacking.

To treat or not to treat

In 1996, the Royal College of Physicians issued a consensus statement indicating that there was little agreement on whether subclinical hyperthyroidism caused morbidity, and thus the benefits of detecting it remain unclear.¹⁶ Since that time, increasing evidence for associated morbidity and mortality (described above) is leading to the view that intervention (reduction in T4 dosages or consideration of antithyroid medication) is important.

Practically, it is sensible to repeat TFTs on a six monthly basis in those who have endogenous subclinical hyperthyroidism where AF and osteoporosis may have been exacerbated by excess thyroid hormone treatment. As these patients are usually elderly, radioiodine is the treatment of choice unless contraindications exist.

HYPOTHYROIDISM

Hypothyroidism results from insufficient production and secretion of thyroid hormones. This may be due to disturbance within the thyroid gland itself (primary hypothyroidism), or within the hypothalamic-pituitary-thyroid axis (secondary hypothyroidism). The causes of primary and secondary hypothyroidism are summarized in Table 28.10. Primary autoimmune hypothyroidism is by far the commonest cause.

The term **myxoedema** is not synonymous with hypothyroidism and refers to the accumulation of glycosaminoglycans occurring in severe hypothyroidism. These hydrophilic substances are deposited within the dermis leading to induration of the skin and the characteristic facial features of hypothyroidism.

Epidemiology

As in other autoimmune conditions, hypothyroidism affects females more commonly than males and its

Table 28.10 Causes of primary and secondary hypothyroidism.

Primary				Secondary			
Associated with goitre (TSH raised, T4 low)	Not associated with goitre (TSH raised, T4 low)	Self-limiting		Hypothalamic (TSH low, T4 low)		Pituitary (TSH low, T4 low)	
Hashimoto's thyroiditis (chronic thyroiditis)	Atrophic thyroiditis	Transient thyroiditis	Subacute, or silent thyroiditis	Congenital	Lack of TRH	Congenital	Lack of TSH
Iodine deficiency (affects 800 million worldwide)	Iatrogenic, e.g. radioiodine, surgery, neck irradiation	Post-partum thyroiditis		Infiltrative	Sarcoidosis, tuberculosis, primary or metastatic malignancy	Panhypopituitarism	Pituitary tumour, cranial irradiation, infection, inflammation
Inherited defects of biosynthesis	Congenital anomaly, e.g. thyroid agenesis	Iatrogenic	Overtreatment with antithyroid medication	Infective	Encephalitis		
Maternal transmission, e.g. antithyroid agents	Drug induced, e.g. amiodarone, lithium, iodides, phenylbutazone						

incidence peaks in the 40–50 year age group, although it can occur at any age and juvenile hypothyroidism is not uncommon. The prevalence of hypothyroidism is estimated at around 2 percent of adult women and 0.2 percent of men.¹ Primary hypothyroidism accounts for 95 percent of cases with less than 5 percent being due to a lack of TSH.

Neonatal hypothyroidism, which if untreated results in severe intellectual impairment, occurs in around 1 in 4000 births and is routinely screened for in the post-natal period in the UK. At the other end of the spectrum of age, the incidence of hypothyroidism in the elderly is around 5–10 percent in women over 65. The symptoms may be nonspecific or falsely ascribed to increasing age, thus a high index of suspicion should exist in this group of patients and some advocate routine screening for hypothyroidism in the elderly.

Clinical features of hypothyroidism

An insufficiency of thyroid hormone affects almost every organ system in the body and the effects of hypothyroidism can be broadly divided into two: firstly the generalized slowing of all metabolic processes leading to, amongst others, fatigue, cold intolerance and weight gain; secondly, the tissue accumulation of glycosaminoglycans, which leads to characteristic changes such as coarse dry skin, hair loss and doughy peripheral oedema. Manifestations of and laboratory findings in hypothyroidism are listed in Table 28.11.

The onset of symptoms may be insidious and go unrecognized, such that severe myxoedema may result. The typical patient complains of lethargy and fatigue, and

these complaints, plus the accompanying apathy and listlessness, mean that the ability to work is impaired. There may be a slow increase of weight despite a reduction in appetite and constipation is a common feature. Cold intolerance is typical with the patient wearing layers of clothes at initial consultation.

There may be a husky gruff voice attributed to 'laryngitis' but resulting from oedema of the vocal cords. Women may complain of dry coarse hair and brittle nails. Menstrual periods may be heavy and a desired conception elusive.

Myopathy may cause difficulty in walking upstairs or rising from a chair and numbness and paraesthesia in the hands may develop as carpal tunnel syndrome results from peripheral oedema. Occasionally, neuropsychiatric complications may develop with bizarre behaviour, so-called 'myxoedema madness', although this condition is now uncommon and confined to historical literature, which probably reflects earlier diagnosis and therapy. This is to be distinguished from a myxoedema coma, which is a life-threatening condition often precipitated by infection, trauma or cold and occurring most often in older patients (see Table 28.8).

Aetiology of hypothyroidism

CHRONIC AUTOIMMUNE HYPOTHYROIDISM/HASHIMOTO'S THYROIDITIS

This condition is the most common cause of hypothyroidism in areas replete with iodine. It occurs in around 3.5 per 1000 per year in women and less than 1 per 1000 per year in men. It is, in many respects, the archetypal

Table 28.11 Manifestations and laboratory findings in hypothyroidism.

Symptoms	Signs	Laboratory findings
Weakness/fatigue	Pale cool skin	Low serum free T4 concentration
Periorbital oedema	Characteristic facial features	Mild hyponatraemia
Constipation	Peripheral/facial oedema	Usually raised TSH concentration
Myopathy	Bradycardia	Positive thyroid microsomal autoantibodies
Slow/hoarse speech	Slow relaxing tendon reflexes	If TSH concentration suppressed consider central lesion
Menorrhagia	Hoarse voice	Normochromic normocytic anaemia
Coarse dry skin	Goitre	Raised serum cholesterol, triglycerides, LDL
Loss/drying of hair		Lowered HDL (atherogenic lipid profile)
Cold intolerance		Raised serum prolactin
Peripheral oedema		
Carpal tunnel syndrome		
Ovulatory failure		
Pale skin/flush (peaches and cream)		
Coarse facial features		
Decreased appetite with weight gain		
Intellectual impairment

Galactorrhoea		

autoimmune condition and is commoner in females, running in families where a history of Graves' disease may feature along with other autoimmune conditions, such as vitiligo, pernicious anaemia, rheumatoid arthritis and type 1 diabetes mellitus. Although it is most common in older women, it can occur in infants as young as two years of age and is the major cause of hypothyroidism in children.

First recognized in 1912, the pathogenesis of the condition is now relatively well understood. Both cell-mediated and humoral factors contribute to the destruction of the thyroid gland. T cell infiltration is pronounced with cellular injury resulting from direct action by cytotoxic T cells.

Although patients have high circulating antibodies to thyroid microsomes and to thyroglobulin, these are not thought to have functional activity. Histologically, the gland is infiltrated with lymphocytes and areas of follicular destruction and fibrosis may be evident. Enlarged epithelial cells with oxyphilic changes in the cytoplasm and Askanazy cells are commonly found in this condition (Figure 28.8).

Initially, the thyroid hypofunction may be subclinical, but may become overt with a rate of developing hypothyroidism at a rate of around 5 percent per year. A slowly growing goitre may have been found on examination or noted by the patient or a family member.

The typical goitre is moderate in size and smooth. Although both lobes are affected, the gland may appear asymmetrical. The presence of the goitre may predate the development of overt hypothyroidism and, generally, the goitre remains static or may decrease in size. Some patients present without a palpable goitre and are said to have atrophic autoimmune thyroiditis, which is thought to represent the end point of Hashimoto's thyroiditis.

IATROGENIC HYPOTHYROIDISM

Iatrogenic hypothyroidism may result from surgery, treatment with radioactive iodine and external beam radiotherapy, such as used in lymphoma. Occasionally, hypothyroidism can result from overtreatment of hyperthyroidism with antithyroid medication, but with close monitoring this is not common.

Thyroidectomy

After total thyroidectomy hypothyroidism would be evident without treatment at around two to four weeks postoperatively, thus all patients who have undergone total thyroidectomy commence thyroid hormone replacement before leaving hospital. Hypothyroidism may also result from subtotal thyroidectomy with the majority of patients becoming so within a year of surgery.

Radioiodine therapy

This can lead to transient hypothyroidism resulting from radiation thyroiditis some four to six weeks after treatment, or permanent hypothyroidism may ensue months or years after therapy.

External beam neck irradiation

Radiotherapy given to the neck may result in both hypothyroidism and an increased risk of thyroid malignancy, especially in children and adolescents.

For patients who have had more than 25 Gy there may be a slow onset dose-dependent development of hypothyroidism.²⁷ Such patients should be carefully monitored for both the hypothyroidism that may initially be subclinical, and for nodular thyroid disease which may herald a thyroid malignancy.

IODINE DEFICIENCY AND THE THYROID

Iodine deficiency is the most common cause of hypothyroidism and goitre worldwide. In 1993, the World Health Organization estimated that 29 percent of the world's population live in areas of iodine deficiency.²⁸ Around eight million people have some degree of deficiency in iodine intake and 200 million are at high risk. Low iodine intake leads to impaired production and secretion of thyroid hormones, resulting in a raised serum TSH which stimulates thyroid growth. Diets high in goitrogens, such as cassava and some soya beans, can exacerbate the situation. Affecting those living in mountainous areas, it may result in neonatal cretinism, a combination of intellectual impairment, ataxia, coarse facies and deaf mutism. Poor performance and deafness in children can result from marginal iodine deficiency in iodine-deficient regions. Goitres may be present from young adulthood and can enlarge causing obstructive symptoms.

Iodine requirements are around 60–100 μg daily, and in the USA iodine is added to salt giving an intake of

around 500 µg, thus goitre due to iodine deficiency is extremely rare. Occasionally seen in Europe where less iodine is added to salt, goitre may also be seen in those migrating from areas where iodine intake is low, such as Pakistan and Bangladesh.

CENTRAL HYPOTHYROIDISM

Lack of hypothalamic thyrotropin releasing hormone (TRH) or pituitary TSH may lead to hypothyroidism, although central hypothyroidism accounts for less than 1 percent of all cases of hypothyroidism. The commonest cause is a tumour in the hypothalamic/pituitary region, isolated TSH or TRH deficiency being very rare. Such central causes may be distinguished from primary hypothyroidism by a normal or low-serum TSH concentration that is inappropriate given a low-serum T3 and T4 concentration. Approximately a third of patients with central hypothyroidism display marginal elevation of TSH which is bioinactive.

Those with a pituitary adenoma may have other features of hypopituitarism, such as hypogonadism and hypoadrenalism, obscuring the symptoms of thyroid hormone deficiency.

Treatment of hypothyroidism

PHARMACOLOGY OF THYROID HORMONE REPLACEMENT

Thyroxine is the drug of choice for the treatment of hypothyroidism. [***] [Grade B] It is absorbed from the upper small bowel with approximately 80 percent efficiency and has a long enough half-life (seven days) to allow for daily or even weekly dosing if compliance is an issue. Thyroxine is a prohormone which is deiodinated in peripheral tissues to the active hormone T3. T3 has a ten-fold higher affinity than T4 for thyroid hormone receptors.

ADMINISTRATION AND MONITORING OF THERAPY

The aim of treatment is to return the patient to a euthyroid state both clinically as judged from symptoms, and biochemically as judged from serum TSH estimations. The average daily dose is around 125 µg daily but variation exists, typical doses required to achieve euthyroidism being 100–150 µg. In those less than 50 years of age with no evidence of ischaemic heart disease, a moderate dose (typically 100 µg) may be started immediately. In older patients, or those with known cardiac disease, a starting dose of 25 µg is prudent due to the risk of exacerbating or precipitating cardiac disease because of the rise in cardiac output associated with initiation of therapy. Increments of 25 µg can be added every four to six weeks until TSH concentrations are within the normal range. Due to the long half-life of thyroxine, four to six weeks should elapse before measuring TSH concentration

after initiating therapy or after dose adjustment. Once stable, serum TSH needs to be checked on an annual basis to ensure ongoing compliance.

In those with central hypothyroidism, it is imperative that hypoadrenalism be excluded before initiating thyroxine therapy. An adrenal crisis may be precipitated if hypoadrenalism is not treated before thyroxine therapy is commenced. In central hypothyroidism, the serum TSH concentration is of no value in monitoring therapy, thus dose adjustments should be made on serum T4 and T3 levels alone.

SITUATIONS REQUIRING ALTERATION OF THYROXINE DOSE

Elderly patients

Thyroxine therapy should be started at a dose of 25–50 µg daily and increased every four weeks until stable. Overtreatment, resulting in a suppressed TSH concentration, should be avoided due to the risk of precipitating atrial fibrillation.

Pregnant women

Women need more thyroid hormone during pregnancy and those with pre-existing hypothyroidism cannot increase T4 and T3 secretion as can normal women. Hypothyroid women need around 40 percent more thyroxine in pregnancy and serum TSH concentration should be measured at least in each trimester throughout the pregnancy and doses titrated accordingly. Most increases are needed in the second and third trimester when the baby is growing faster.

Patients with poor compliance

Due to the long half-life of thyroxine, poorly compliant patients may be witnessed taking seven days of thyroxine once a week.

Patients preferring T3 therapy

Some patients feel that their symptoms of hypothyroidism are not controlled on thyroxine therapy despite normal concentrations of TSH and T4. Some choose to take T3 in addition to or instead of thyroxine, although due to its rapid absorption and short half-life it must be taken three times a day and fluctuations in thyroid hormone levels exist. At present there is little evidence to suggest advantage over T4 therapy and is probably best avoided.²⁹

Subclinical hypothyroidism

The term 'subclinical hypothyroidism' is used to describe a state where there is a raised TSH concentration with a normal concentration of T4. It is essentially a biochemical diagnosis. Subclinical hypothyroidism is relatively common with data from population surveys estimating a prevalence of 7–8 percent in women and 2–4 percent in men. The

prevalence rises with age to approximately 15 percent in women over 60. It is also more common in those with other autoimmune conditions.

AETIOLOGY

Often this may be clear from the history, for example in those who have previously been treated with radioactive iodine or who have had a subtotal thyroidectomy. The patient may be already known to be hypothyroid and replacement may be suboptimal or compliance an issue.

A history of autoimmune disease, either in the patient or in close relatives, suggests autoimmune (Hashimoto's) thyroid disease. Around 60 percent of women with subclinical hypothyroidism have positive antibodies to thyroid peroxidase in the UK.

Prospective studies have confirmed that those with both positive antibodies and elevated TSH concentration are at risk of developing overt hypothyroidism at the rate of around 5 percent per year,³⁰ the risks being higher for those aged over 60.

MANAGEMENT

Controversy exists as to who should be treated and at what point, as the risks of inappropriate overtreatment to bone and cardiovascular system have been outlined. Recent guidelines state that apart from the fair data relating raised TSH to cholesterol, data showing clear benefits of treatment are lacking.³¹ Many clinicians would treat if there were symptoms, a raised TSH over 10 mU/L and positive autoantibodies, due to the high risk of progression to overt hypothyroidism. For asymptomatic patients with a modestly raised TSH (below 10 mU/L) or with a low or negative titre of microsomal antibodies, retest on a six monthly basis is advised.

KEY POINTS

- Hypothyroidism affects 2 percent of adult women but its prevalence rises with age.
- Symptoms are due to an accumulation of glycosaminoglycans in soft tissues and a general slowing of all body processes.
- Chronic autoimmune (lymphocytic) thyroiditis (Hashimoto's) is the most common cause but iatrogenic hypothyroidism is also common.
- Thyroxine is the treatment of choice and treatment is usually lifelong.
- Instigation of treatment should be cautious in those where cardiac problems may be exacerbated.

Best clinical practice

Investigation of hypothyroidism

- ✓ Measure T4, TSH and thyroid autoantibodies in suspected hypothyroidism.
- ✓ Ultrasound/nuclear medicine scans are not helpful.
- ✓ Refer to an endocrinologist if atypical features or other concerns.

Treatment of hypothyroidism

- ✓ Treat with thyroxine if hypothyroidism confirmed.
- ✓ In the elderly or those with cardiac dysfunction reduce the starting dose.
- ✓ Monitor to ensure TSH remains in the normal range.
- ✓ In hypothyroidism due to pituitary disease TSH is unhelpful. Monitor T4 levels.
- ✓ There is no evidence supporting the use of T3 in addition to or instead of T4.
- ✓ Treat subclinical hyperthyroidism if symptomatic and TSH over ten. If TSH below ten, re-test periodically.

THYROID DISEASE IN PREGNANCY

Hyperthyroid states in pregnancy

POST-PARTUM THYROIDITIS

The immunological changes associated with pregnancy and delivery can affect thyroid status in different ways. Those with pre-existing disease may find symptoms are aggravated or ameliorated at different times during the pregnancy.

Post-partum, around 5 percent of women develop thyroid dysfunction.³² The risk is higher in those who have positive thyroid antibodies, type 1 diabetes mellitus (25 percent), a family history of thyroid disease or another coexisting autoimmune condition.

Of those who develop post-partum thyroid dysfunction, around one-third have post-partum thyroiditis, with symptoms of thyrotoxicosis at around 12 weeks post-delivery, followed by a period of hypothyroidism at around three to six months. In some women, only the hypothyroid phase is evident and eventually there will be a return to a euthyroid state. Histologically, there is a destructive thyroiditis with a florid lymphocytic infiltrate seen at around 16 weeks in those who are antibody positive. The remainder of patients with post-partum thyroid dysfunction may present with either Graves' disease or Hashimoto's thyroiditis. In those with biochemical and clinical thyrotoxicosis developing later than three to six months post-partum, Graves' disease is more likely, and in these cases the hyperthyroidism will be sustained.

Iodine uptake measurements are the investigation of choice and can help to distinguish between post-partum thyroiditis and Graves' disease. The distinction is important, as treatment choices will differ according to the aetiology of thyroid dysfunction. Those with post-partum thyroiditis will show reduced uptake on scintigraphic scanning whereas those with Graves' disease will show elevated uptake. Breast-feeding should be avoided for only 24 hours if ^{99m}Tc is used.

Post-partum thyroiditis may be managed symptomatically with propranolol if necessary but Graves' disease is treated with thionamides. PTU is excreted less than carbimazole into breast milk and is preferred if breast-feeding is continued. Treatment of the hypothyroid phase may be needed in around a third of women and T4 may be necessary for up to 12 months.

Long term, patients who have experienced post-partum thyroiditis are at risk of further episodes in subsequent pregnancies, as well as having a high risk (over 50 percent) of developing long-term hypothyroidism. These women need follow-up with annual TFTs.

TRANSIENT HYPERTHYROIDISM OF HYPEREMESIS GRAVIDARUM

Transient thyrotoxicosis may be seen in cases of hyperemesis gravidarum, the likely mechanism being the raised beta human chorionic gonadotropin (HCG) level. Beta HCG and TSH are glycoproteins consisting of an alpha and beta subunit. The alpha subunit is common to these and other anterior pituitary hormones, whilst the beta subunit is hormone specific. Beta HCG concentrations rise to a peak at 10–12 weeks of pregnancy and then decline.

During this time there is stimulation of the TSH-receptor and increased production of T3 and T4. When HCG is at its highest, 10–20 percent of normal women have low-serum TSH. Women with hyperemesis gravidarum have higher HCG and estradiol concentrations than those without and around 60 percent show a raised serum T4 concentration with a suppressed serum TSH. Management is supportive and antithyroid medication should be avoided.

Thyrotoxicosis associated with hyperemesis can be distinguished from Graves' disease by a negative family history, a lack of any other autoimmune illnesses, negative thyroid antibodies and an absence of physical signs specifically associated with Graves' disease, such as eye signs and a diffuse goitre.

GRAVES' DISEASE IN PREGNANCY

Graves' disease accounts for around 90 percent of cases of thyrotoxicosis observed in pregnancy. Around two in every thousand women are affected. Menstrual irregularities, difficulties in conception and an increased rate of

miscarriage are seen in women with thyrotoxicosis and women should be advised to delay pregnancy until euthyroid. Pregnancy in women who are biochemically hyperthyroid is not uncommon, and occasionally Graves' disease develops *de novo* in pregnancy. The diagnosis of thyrotoxicosis may be delayed as symptoms and signs may be wrongly attributed to physiological changes occurring in pregnancy, such as increased metabolic rate, increased cardiac output, heat intolerance and mood changes. Other symptoms may include hyperemesis gravidarum, muscle fatigue and, occasionally, cardiovascular problems such as pregnancy-induced hypertension or high output cardiac failure.

Treatment of thyrotoxicosis in pregnancy aims to achieve rapid biochemical euthyroidism whilst alleviating symptoms. Propranolol may be used as an adjunct but the mainstay of treatment is antithyroid medication, as radioiodine is contraindicated in this situation. PTU is preferred to carbimazole, being more strongly bound to plasma proteins; less drug is delivered to the foetus. In the rare instance of a serious adverse reaction to thionamides, surgery may be performed, preferably in the second trimester.

Joint management with the endocrinologist, obstetrician and paediatrician is important as there is a risk of foetal and neonatal thyrotoxicosis indicated by low birth weight, irritability and tachycardia.

Hypothyroid states in pregnancy

Overt hypothyroidism presenting at conception and in early pregnancy is relatively rare, largely as a result of a combination of anovulation and first trimester abortion which are associated with overt thyroid hormone deficiency. For those women who develop the condition in pregnancy, overt hypothyroidism can have adverse effects on both mother and foetus with increasing risks of pre-eclampsia, placental abruption, low birth weight and an increased perinatal mortality.

Considerable debate and concern surrounds the potential effect of mild or 'subclinical' hypothyroidism, indicated by raised serum TSH with normal free T4 concentrations, or indeed those with slight reductions in free T4 alone. Recent studies have shown mild but statistically significant adverse neuropsychological effects in children born to mothers with raised TSH in the first trimester. One study showed a decreased IQ in children born to mothers where the TSH was greater than the 98th centile, i.e. severe hypothyroidism.³⁵ Another study has shown a delay in psychomotor functioning in children born to women with T4 levels below the 10th centile at 12 weeks. Many of these neurocognitive deficits may be explained by prematurity or reduced placental function, and these studies have led to debate regarding screening for thyroid dysfunction in pregnant women. Current opinion is that only targeted screening should be

undertaken, for example those with a previous or family history of thyroid disease or those with type 1 diabetes mellitus, but this approach may change as the evidence base increases.

TREATMENT OF HYPOTHYROIDISM IN PREGNANCY

During pregnancy, the requirement for thyroid hormone increases for many reasons including weight gain, transfer of T4 to the foetus and the raised concentration of thyroxin binding globulin.

Around three-quarters of women with treated hypothyroidism will need an increased dose during pregnancy, often by around 50 percent and sometimes as early as five weeks gestation. Most clinicians would measure TFTs around four to six weeks gestation, six weeks after any increase in dose of T4 and at least once per trimester. Post-delivery, the dose can be reduced to prepregnancy levels and checked to ensure it was sufficient.

Best clinical practice

- ✓ Thyroid disease in pregnancy should be jointly managed by an endocrinologist, obstetrician and paediatrician.
- ✓ Hyperemesis may be associated with transient thyrotoxicosis – treat supportively.
- ✓ Graves' disease in pregnancy should be treated with thionamides. Propylthiouracil is preferable to carbimazole.
- ✓ Aim to keep TSH in the normal range in pregnant hypothyroid women. They require frequent TFTs and usually need an increase in thyroxine.
- ✓ Post partum thyroiditis is common. Measure TFTs and antibodies in symptomatic women. Referral and treatment may be required.

NONMALIGNANT EUTHYROID CONDITIONS

Nodular thyroid disease

EPIDEMIOLOGY AND AETIOLOGY

Nodular thyroid disease describes the presence of a single or multiple nodules within the thyroid gland. These nodules may be palpable or impalpable, functioning or nonfunctioning. Functioning solitary nodules are those that synthesize thyroid hormones autonomously and thus may lead to thyroid hormone excess and symptoms of thyrotoxicosis. Aetiology, diagnosis and management are covered in detail under Thyrotoxicosis.

Thyroid nodules and goitre are very common. Lifetime risk for the development of a palpable nodule is

approximately 10 percent, but prevalence may be as high as 50 percent depending on the imaging methods used. Nodules are more frequent in women and prevalence increases with age, exposure to ionizing radiation and iodine intake. The causes of thyroid nodules are listed in Table 28.12. The difficulty facing the clinician is to differentiate between the vast majority of benign lesions and the smaller proportion (between 5 and 6 percent) of malignant neoplasms.

In those with thyroid nodules, malignancy is more likely in those below 20 and above 60 years of age, in those with a previous history of neck irradiation and in men (although the majority of nodules occur in women). It is more common in those with a history of Hashimoto's thyroiditis, which is associated with lymphoma, and those with a family history of multiple endocrine neoplasia syndromes 2a and 2b (associated with medullary carcinoma). Those giving a history of a rapidly enlarging painless lesion, dysphonia or dysphagia should be viewed with high clinical suspicion. The factors suggesting malignancy in a thyroid nodule are listed in Table 28.13.

MULTINODULAR GOITRE

Data from the Whickam Survey in an iodine-replete region indicated the presence of a small goitre in 8.6 percent, a palpable goitre in 15 percent and a visible goitre in a further 7 percent,¹ the majority of lesions occurring in premenopausal females. TSH and thyroid hormones

Table 28.12 Causes of thyroid nodules.

Benign	Malignant
Colloid cyst	Papillary carcinoma
Simple cyst	Follicular carcinoma
Subacute thyroiditis	Medullary carcinoma
Infection, e.g. TB	Nonthyroidal malignancy
Lymphoma	Metastases
Follicular adenoma	Breast
Hurthle cell adenoma	Renal

Table 28.13 Factors suggesting malignancy in a thyroid nodule.

Highly suspicious	Moderately suspicious
Rapidly enlarging painless mass	Age <20 or >60
Firm or hard lesion	Male gender
Fixation to underlying structures	Solitary nodule
Vocal cord paralysis	Previous head or neck irradiation
Palpable lymphadenopathy	Compression symptoms, cough, dysphagia, dyspnoea
Family history of MEN 2a or 2b	Hashimoto's thyroiditis

did not differ significantly between those with and without goitres. When the same subjects were studied 20 years later, it became evident that the prevalence of goitre had fallen, confirming that a proportion may regress and thus treatment is not always necessary.³⁰

Patients may present because the lesion was noticed by themselves, a family member or a health care professional. Many patients are asymptomatic and seek reassurance that all is well. Others may have symptoms suggesting thyroid hyperfunction, the investigation and management of which has previously been outlined. Those with a sizeable goitre may be unhappy with the cosmetic appearance of the lesion or may present with pressure and symptoms such as dysphagia, breathlessness and very occasionally, stridor.

Physical examination should focus on the size and consistency of the goitre with special attention to the presence or absence of dominant nodules, factors suggesting malignancy such as a fixed mass, lymphadenopathy and signs of invasion, such as dysphonia and stridor (Table 28.13)

INVESTIGATION OF NODULAR THYROID DISEASE

Modalities of investigation will, to some extent, depend on the clinical situation. For example, a flow volume loop may be appropriate in those with a large goitre and respiratory symptoms, a CT may be appropriate for those in whom a significant retrosternal goitre is suspected.

TFTs, antibody status and calcitonin

TFTs are frequently the first investigations in nodular thyroid disease. Those with suppressed TSH and elevated thyroid hormones should be investigated and treated as outlined previously, and those with a raised TSH and low T4 also treated accordingly. Biochemical investigation is important as fine needle aspiration cytology (FNAC) should not be performed in those with overt hyper- or hypothyroidism as cytological changes may be difficult to interpret in this setting.

TPO antibodies are also often measured but, in the setting of a euthyroid patient with nodular disease, do not add much to management, other than perhaps identify those at risk for developing thyroiditis or Graves' disease as a result of I^{131} therapy.

Serum calcitonin is elevated in medullary carcinoma of the thyroid but is not a cost-effective screening test in all patients with thyroid nodules. Measurement of calcitonin is best reserved for monitoring patients previously diagnosed with medullary thyroid carcinoma or in those in whom there is a high index of suspicion because of a family history.

FNAC

The mainstay of investigation of thyroid nodules, FNAC is safe, quick, cost-effective and has a high degree of diagnostic accuracy. FNAC is an outpatient procedure, best carried out by an experienced operator, with or without local anaesthetic and a 24–27 g needle. Samples should be interpreted by an experienced cytopathologist and may be graded as benign, malignant, suspicious or nondiagnostic. Nondiagnostic samples are obtained in around 15 percent depending on the operator (Figure 28.9).

FNAC in expert hands is very reliable, with studies showing overall diagnostic accuracy of between 85 and 100 percent, with specificity for the diagnosis of neoplasia of 72–100 percent and sensitivity of 65–98 percent. In a series of over 800 subjects, accuracy of FNAC was over 95 percent, with a false positive rate for malignancy of 2.3 percent, and a false negative rate of 1.1 percent,³⁴ rates that have been confirmed by others.³⁵ An important limitation of FNAC is the inability to distinguish benign from malignant follicular lesions, determining that all such lesions require surgical excision for histological diagnosis. If the patient is managed conservatively, then FNAC is often repeated after three to six months to attempt to further reduce the false negative rate from initial sampling error. Ultrasound has been used to guide FNAC, and in some centres is used routinely, however, the use of ultrasound scanning has not been shown to significantly increase diagnostic accuracy over FNAC guided by palpation.³⁶ Outcomes of FNAC are shown in Table 28.14.

Thyroid scintigraphy

Scintigraphy is of little value in the differentiation between benign and malignant nodular disease. This is because the majority of nodules trap isotope (Tc^{99} or I^{123})

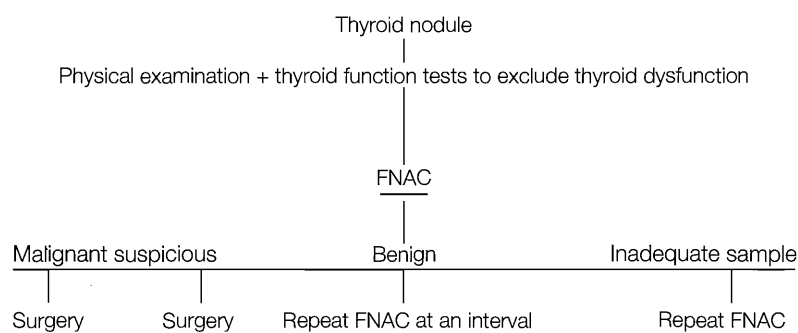

Figure 28.9 Algorithm for investigation of solitary thyroid nodule.

Table 28.14 Outcomes of fine needle aspiration cytology.

Category	Diagnosis	Percentage of samples	Range
Benign	Colloid nodule	60	53–90
	Hashimoto's thyroiditis		
Suspicious	Cellular adenoma	15–20	5–23
	Follicular neoplasm		
	Hurthle cell (oxyphilic) change		
Malignant	Papillary carcinoma	< 10	1–10
	Medullary carcinoma		
	Follicular carcinoma		
	Nonthyroidal malignancy		
	Insufficient/ nondiagnostic sample (can be halved with repeat FNAC)	17	15–20

less well than normal thyroid tissue, so appearing ‘cold’ on scintigraphy, yet the incidence of cancer in cold nodules is only approximately 10 percent. Scintigraphy is thus poorly specific for the diagnosis of thyroid neoplasia. Cost-effectiveness analyses have shown that where scintigraphy precedes FNAC, a delay in diagnosis occurs from 6.9 days from FNAC alone (in clinically euthyroid patients) to 17.7 days, and adds considerably to the cost of investigation.³⁷ Both the British Thyroid Association and the American Thyroid Association have published guidelines stating that scintigraphy has no role in the routine management of the thyroid nodule.^{38, 39}

Ultrasound scanning

Ultrasound scanning has the ability to delineate the anatomy of the thyroid gland and some characteristics may indicate an increased likelihood that a nodule is malignant, for example the presence of microcalcification, hypervascularity and capsular invasion. It also allows the detection of other nodules in a gland where only one is palpable, additional nodules being found in around 40 percent, thought on palpation to harbour a single palpable lesion. The high sensitivity of ultrasonography can, however, lead to an increase in detection of clinically insignificant lesions leading to anxiety and further investigation.

Magnetic resonance imaging and computerised tomography

Both modalities provide high-resolution visualization of the thyroid and adjacent tissues, although do not give additional information about the structure of the thyroid over and above that provided by ultrasonography. Both modalities are useful in the evaluation of large irregular

lesions with a suspected retrosternal component but are not considered useful in the evaluation of the presence and degree of tracheal compression due to variations in tracheal diameter with phase of respiration and position of the patient. With a large goitre, a flow volume loop should always be considered, as asymptomatic tracheal compression is not uncommon.

MEDICAL MANAGEMENT OF NODULAR THYROID DISEASE

Nontoxic multinodular goitre for
Surgery is the treatment of choice where there is evidence of moderate to severe compressive symptoms, where FNAC of a dominant nodule is suspicious of malignancy, or where the patient prefers surgery for cosmetic reasons.⁴⁰
Medical treatment of goitre involves the administration of radioactive iodine; the other medical option of administration of suppressive thyroid hormone is now considered outdated.

Radioiodine therapy

In those with severe compressive symptoms, a large cosmetically unacceptable goitre, or one where there is any suspicion of malignancy, surgery is the treatment of choice. In some patients, however, surgery is not an option either due to age, frailty or other co-morbid conditions, or because the patient refuses surgery. Medical treatment with thyroxine is unattractive for reasons outlined below. Current evidence supports the view that radioiodine is the treatment of choice in this group of patients.
Studies have found that nearly all patients experience a reduction in goitre size, which can be as much as 60 percent, and that although most shrinkage occurs soon after treatment, reduction in size can continue for some years after treatment. Most patients experience relief from obstructive symptoms with dyspnoea improving in three-quarters of those with the largest goitres, accompanied by an increase in cross-section area of the trachea of 36 percent.⁴¹
Factors suggesting a favourable outcome include smaller goitres in younger patients, a shorter history of goitre and higher doses of radioiodine. In those with large goitres, large doses of radioiodine may be necessary, which, due to radiation protection legislation, can entail the hospitalization and isolation of the patient. An alternative is to fractionate therapy over a course of some months in an outpatient setting.

Side effects of radioiodine therapy for multinodular goitre
Radiation thyroiditis (neck pain and tenderness) is uncommon, studies suggesting an occurrence of between 3 and 13 percent. Graves’ type hyperthyroidism associated with development of TSH receptor antibodies may occur after radioiodine administration and is usually transient.

Occurring in around 5 percent, it is more common in those with high titres of thyroid peroxidase antibodies prior to radioiodine treatment.

Hypothyroidism, either transient or permanent, is not uncommon. The prevalence varies according to the amount of radiation exposure, with figures quoted ranging between 8 and 40 percent at one to two years. The use of multiple fractionated doses of radioiodine may significantly increase the risk of hypothyroidism.

There has been concern over the risk of deterioration in respiratory function in those with tracheal compression after I^{131} administration due to a transient increase in goitre size immediately after therapy. Studies have shown only a small decrease in tracheal cross-sectional area after therapy with no deterioration of inspiratory function. Some recommend the use of prednisolone peri- and post- I^{131} to minimize any risks in those with severe tracheal compression, but there is no evidence base for this practice.⁴⁰

New approaches to radioiodine treatment of nontoxic multinodular goitre

Recombinant TSH may be used in this setting. The logic is that the higher the serum TSH, the greater the stimulus for radioiodine uptake into the goitre and the greater the chance of efficacy with a lower overall dose of radioiodine. Although preliminary results are encouraging,⁴² evidence for efficacy in volume reduction is not yet available, so recombinant TSH is not widely used at present.

Thyroid hormone suppressive therapy

Suppressing TSH secretion in those with goitres may result in a reduction in size of the lesions, as TSH is necessary for goitre development. This practice, first carried out in the late nineteenth century, fell out of favour until the mid-1950s. Although some studies have shown benefit, growth of thyroid nodules or goitres often resumes after discontinuation of thyroxine, meaning therapy may need to be lifelong. Suppressive therapy necessarily induces a state of subclinical hyperthyroidism (suppression of TSH) with risks of AF and reduced bone density, as previously outlined. For this reason, the use of suppressive therapy has been abandoned by most thyroidologists.⁴⁰

Solitary nontoxic nodule

Much of the treatment of the solitary thyroid nodule has been covered elsewhere and is effectively similar to the treatment of multinodular goitre. Surgery remains the treatment of choice in those who desire it for cosmetic reasons, and in those whom malignancy is suspected either on clinical grounds or on the basis of cytological changes suggestive or suspicious of neoplasia. Suppressive therapy with thyroid hormones is not recommended for solitary nodules for reasons previously discussed.

Radioiodine therapy

This is a simple, safe and cost-effective treatment for those with solitary thyroid nodules which take up iodine (hot nodules) and a thyroid volume reduction of 40 percent may be seen after a single dose of I^{131} . Hypothyroidism is relatively rare with a prevalence of around 10 percent at five years and is higher in those with pre-existing thyroid autoimmunity.

Cystic nodules

These comprise around 10–15 percent of solitary thyroid nodules and simple aspiration is the treatment of choice, however, recurrence rates may be as high as 80 percent with larger lesions. For this reason, and the fact that many cysts resolve spontaneously over time, an expectant approach may be taken with small cysts less than 3 mL. Larger ones should be aspirated with FNAC performed on any residual nodule and surgery considered, as around 10 percent of large lesions may harbour thyroid cancer.

Thyroid incidentalomas

These are nodules detected on routine imaging for other conditions, such as Doppler ultrasound of the carotid arteries and CT or MRI of the head and neck. In nodules of less than 1.5 cm the risk of carcinoma is less than 5 percent, and it remains unclear whether incidentally found (and small) nodules require further investigation. If FNAC is contemplated, then ultrasound guidance may be necessary, as the majority of nodules will be impalpable.

New approaches to the management of solitary nodules

In some specialist centres, injection of ethanol into solitary nodules appears to be effective in causing shrinkage due to coagulative necrosis.⁴³ Problems with this therapy include seepage of ethanol outside the lesion damaging adjacent tissue, a painful rise in pressure inside the nodule and development of thyroid autoimmunity. For these reasons the procedure should be regarded as experimental.

Ethanol can also be injected into cystic lesions and a short-term placebo-controlled study has been promising with success rates for shrinkage of up to 80 percent.⁴⁴ Side effects seem less than those seen in injection into a solid lesion but the practice is not yet widespread.

KEY POINTS

- Thyroid nodules are common and occur singly or as part of a multinodular goitre.
- Nodules may function autonomously producing thyroid hormones, a small proportion may be malignant.
- Multinodular goitres may be large and cause compressive symptoms.

- Fine needle aspiration cytology is the investigation of choice in the management of thyroid nodules.
- Surgical excision is necessary where there is any suspicion of malignancy on cytology, for compressive symptoms or cosmesis.
- Medical treatment of multinodular goitre and autonomously functioning nodules with radioiodine is safe and effective.
- Medical treatment of thyroid nodules with thyroxine induces subclinical hyperthyroidism and should be abandoned.

Best clinical practice

- ✓ Assess thyroid status in patients with nodular thyroid disease clinically and biochemically.
- ✓ Refer all nodules for further investigation.
- ✓ Urgent referral if young or older, rapidly enlarging, fixed, invasive or compressive symptoms.
- ✓ Multinodular goitre causing compressive symptoms should be referred.
- ✓ Reserve ultrasonography, FNAC and other investigations for specialist use.

Deficiencies in current knowledge and areas for future research

Further work on the long-term sequelae of thyroid disease, both in the foetus and in adulthood, may add to the debate on screening for thyroid dysfunction, especially in women of childbearing age. Research into Graves' disease pathogenesis centres on identifying genes conferring susceptibility and protection from this disease. Already, major progress has been achieved in identifying the role of specific components of the HLA system and other immune regulatory genes such as CTLA-4, which have functional consequences. Better understanding of the genetic mechanisms leading to this autoimmune disorder may lead to targeted therapies for immune modulation. Such understanding may also allow better prediction of treatment outcomes, for example response to antithyroid drugs and hence better tailoring of therapies for individual patients. The ability to predict outcome in Graves' disease would be of immense clinical value.

Current research into Graves' ophthalmopathy attempts to elucidate the precise aetiology of the condition. Newly developed animal models may have a positive impact in this field. Research into new approaches to treating thyroid eye disease has focused

on the use of cytokine antagonists, somatostatin and analogues and also on the use of antioxidants;⁴⁵ in future it would be expected that double blind trials involving some of these agents may begin.

Importantly, we are beginning to understand the long-term morbidity, and indeed mortality, associated with thyroid dysfunction, largely vascular. This understanding will drive the development of more intensive and effective clinical management strategies and identification of those at particular risk. Future research in nodular thyroid disease will focus on ways of improving the diagnostic pathway to reduce the number of patients undergoing lobectomy for what proves to be benign disease. Current research into ultrasound and colour Doppler criteria for identification of malignancy may have a positive impact. More likely, however, is a major impact of gene expression studies allowing discrimination, perhaps on biopsy specimens, of benign from malignant disease, as well as identification of genetic and molecular markers in resected tumours which will predict potential recurrence and hence the need for intensive therapy.

Introduction	367	Physiology of parathyroid glands	373
Development of parathyroid glands	367	Key points	375
Anatomy of parathyroid glands	369	References	376
Surgical viewpoint	373		

SEARCH STRATEGY AND EVIDENCE-BASE

The data in this chapter are supported by a Medline search using the key words parathyroid glands, anatomy and histology, embryology, physiology, calcium homeostasis, parathyroid hormone. This chapter primarily relies on observational studies and the peer-reviewed literature relating to anatomy and physiology and is therefore level 4 evidence.

INTRODUCTION

The normal parathyroid glands vary in number, location and macroscopic appearance. The principal role of the surgeon in parathyroid surgery is to be able to localize and distinguish diseased from normal parathyroid glands. At present, there are several noninvasive imaging techniques available for aiding the localization of parathyroid tissue. These include high-resolution ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) and dual radioactive isotope scanning (thallium-201/technetium-99m subtraction). However, the precise application of knowledge of the anatomy and embryology of the parathyroid glands is essential to plan an operative strategy and to achieve successful therapy in those patients with parathyroid disease.

Disorders of calcium and bone metabolism are common. Parathyroid hormone (PTH), vitamin D and calcitonin are involved in the maintenance of normal calcium levels by modifying intestinal absorption, renal excretion and bone turnover. A thorough understanding of the physiology and regulation of calcium metabolism is important to the clinician.

DEVELOPMENT OF PARATHYROID GLANDS

The parathyroid glands develop from endodermal cell proliferation of the lateral tips of the third and fourth pharyngeal pouches (Figure 29.1).^{1, 2, 3} The pouches are divided into solid, dorsal bulbar and hollow, elongated ventral portions.⁴ Cell division in the endodermal wall leads to the internal space being obliterated by week six in the embryo. The dorsal aspect of the third pharyngeal pouch forms the inferior parathyroid gland (parathyroid III) and the ventral aspect forms the thymus gland. A duct-like connection exists between the third pharyngeal pouch and the pharyngeal wall which is soon lost, although the connection between the parathyroid and thymic rudiments persists for longer.⁵ The persistence of this connection results in the inferior parathyroid gland migrating inferiorly and medially with the developing thymus gland at the end of the fifth gestational week. At the end of the seventh gestational week, the inferior parathyroid gland is located in its normal position dorsal to the inferior aspect of the thyroid lobes (Figure 29.2a and b).⁶ The inferior parathyroid gland can become adherent to the thyroid capsule at this early stage of

Figure 29.1 Embryology of the parathyroid glands. Schematic posterior view of the pharyngeal arches. Pharyngeal pouches are numbered 1 to 4.

development. The thymus gland ultimately migrates to the anterior mediastinum.

The dorsal aspect of the **fourth pharyngeal pouch forms the superior parathyroid gland** (parathyroid IV). The ventral aspect of the pouch and the remnants of the fifth pharyngeal pouch form the ultimobranchial bodies, which form C (parafollicular) cells. The ultimobranchial bodies appear to be analogues of parathyroid tissue and play a role in calcium metabolism with their embryological origin supporting this. The C cells ultimately fuse with the thyroid gland and are sometimes termed the lateral thyroid (**Figure 29.2a and b**).¹

The superior parathyroid gland begins to migrate caudally and medially at the end of the fifth gestational week to reach its final anatomical position posterior to the lateral thyroid lobes at a point where the inferior thyroid artery enters the gland or at a point of intersection of the artery and the recurrent laryngeal nerve.

The pathway of embryological descent of the superior and inferior parathyroid glands along the thyro-thymic axis is shown in **Figure 29.3**. The superior parathyroid gland is usually located above the inferior thyroid artery and behind the recurrent laryngeal nerve, whereas the inferior gland is usually below the inferior thyroid artery and in front of the

Figure 29.2 Schematic views of shifts in location of parathyroid tissue during embryological development. *Also known as lateral thyroid – contains C (parafollicular) cells.

recurrent laryngeal nerve (**Figure 29.4a**). This migration is complete at the end of the seventh gestational week.⁶

The migratory pathways of the parathyroid glands during embryological development result in many variations in their final anatomical location. The caudal migration of the superior parathyroid gland is less in comparison to the migration of the inferior parathyroid gland which is associated with the descent of the thymus gland, thus explaining their paradoxical positioning. This is the reason for the increased proportion of anomalies of position of the inferior parathyroid gland.

There is some controversy regarding the embryological origin of the parathyroid glands from the ectodermal (epipharyngeal) placode. The parathyroid glands have been classified as part of the amine precursor uptake and decarboxylation (APUD) system.^{7,8} Protein SP-1 has been found to be secreted with PTH and is analogous to chromogranine-A found in the suprarenal medulla. In

Figure 29.3 The thyro-thymic axis explains the embryological descent of the parathyroid glands during development and may offer the surgeon a logical pathway to find parathyroid tissue in the neck and superior mediastinum. The majority can be found and identified exploring along the linear thyro-thymic axis. See text for description of anatomy.

addition, pieces of grafted third pharyngeal pouch ectoderm of chick embryos have been shown to develop into distinct parathyroid tissue.⁹ In view of the above it would explain the involvement of the parathyroid glands in the multiple endocrine neoplasia (MEN) syndromes (1 and 2). The above references have been cited for those with further interest in the subject.

ANATOMY OF PARATHYROID GLANDS

The parathyroid glands eluded the notice of anatomists until 1850, when Richard Owen described, 'a small, compact, yellow glandular body that was attached to the thyroid at the point where the veins emerged' at the autopsy of a great Indian rhinoceros. The specimen may be seen today in the Hunterian Museum of the Royal College of Surgeons, England. Independently, in 1877 a Swedish anatomist, Ivar Sandström, described the gross anatomy and microscopic appearance of the parathyroid glands in a dog and subsequently in cat, ox, horse and 50 humans. He suggested the name 'glandulae parathyroideae'.¹⁰

The parathyroid glands vary considerably in number, size, shape, appearance and location.

Number

Typically, there are four parathyroid glands in 80–97 percent of humans.⁴ Gilmour¹¹ dissected 527 autopsy cases, and reported four glands in 80 percent, three in 13 percent, five in 6.1 percent and two in 0.2 percent (one case). Alveryd¹² studied 1405 parathyroid glands (histologically confirmed) from 354 autopsy cases, finding four in 90.6 percent of cases and five in 3.7 percent of cases. Akerström⁴ reported from 503 autopsy cases that four glands were found in 84 percent of cases, more than four in 13 percent and only three glands in 3 percent. Cases of three or fewer glands identified strongly suggested that a fourth gland had been missed. In individuals with four or more glands the supernumerary glands were either rudimentary (2 percent cases) or divided (6 percent cases). Supernumerary glands weighing 5 mg or more were found in 5 percent of cases. The clinical significance of supernumerary glands is that they can be a persistent cause of hyperparathyroidism if not located. However, it is uncommon to find patients with fewer than three or more than five glands.

Size

A normal gland usually measures approximately 5 mm in length, 3 mm in width and 1–2 mm in depth, although, there can be considerable variation. Glands as large as 12 mm and as small as 2 mm have been reported.¹¹ The two lower parathyroid glands are usually heavier than the two upper glands.¹³ Reported maximal weights of normal parathyroid glands vary from 8.2 to 78 mg.^{13, 14, 15, 16} Gland weights also vary with age and gender, being heavier in males and subjects aged 20–30 years, and lighter in females and subjects aged 70–80 years.¹⁴ There is a correlation between increasing gland weight and body weight ($r^2 = 0.15$).¹⁷ Healthy black subjects have heavier glands than healthy white subjects independent of body weight.¹⁷ Size and weight are regarded as important determinants of parathyroid normality.¹¹ A parathyroid gland *in situ* is larger because of its degree of vascularity. Confusion can arise as the weight of a gland reported by the pathologist may be lower than what was expected. In clinical practice, a gland weighing greater than 40–50 mg is considered enlarged.

Shape and macroscopic appearance

The inelasticity of the normal parathyroid gland accounts for its variation in shape and contour. Subcapsular glands located at the upper pole of the thyroid gland have a tendency to be flattened, whereas glands in the cricothyroidal and intrathyroidal regions appear more oval and spherical in shape. Occasionally, a gland is bean, sausage or rod shaped.¹⁴ In contrast, Akerström⁴ documented

Figure 29.4 (a) Cardinal sites to consider first for parathyroid localization, indicating the relationship of the parathyroid glands to the inferior thyroid artery and recurrent laryngeal nerve. Fixed points: parathyroid IV (PIV) – above inferior thyroid artery and behind recurrent laryngeal nerve. Parathyroid III (PIII) – below inferior thyroid artery and in front of recurrent laryngeal nerve. (b) Abnormal sites for parathyroid glands. 1. Carotid sheath – rare and can cause difficulty unless opened exploring the vagus nerve, carotid artery and internal jugular vein. 2. Intrathyroid – rare, but can occur producing recurrent hyperparathyroidism. The majority are subcapsular in location. The clue to exploration is that there is a missing parathyroid gland on that side. In this setting, the surgeon may perform a thyroid lobectomy and find the missing parathyroid gland in the middle of the thyroid. 3. Upper thyroid cartilage. 4. Retropharyngeal/retro-oesophageal. 5. Superior pole of thyroid gland. 6. Paratracheal. 7. Intrathymic. 8. Aortopulmonary window – rare, in these cases a sternotomy needs to be performed and careful excision of the gland in this delicate position. 9. Superior mediastinum.

that the majority of glands were oval, bean shaped or spherical (83 percent of cases), though some glands were elongated (11 percent of cases), bilobed (5 percent of cases) and mutilobed (1 percent of cases). Two parathyroid glands can appose one another forming a 'kissing pair', but this should not be confused with a bilobed gland. The former has a true cleavage plane and a true capsule throughout, which is absent in a bilobed gland. Failure to recognize this anomaly can result in inaccurate accounting of all glands at operation.

The experienced surgeon can identify a parathyroid gland based on its macroscopic appearance and consistency. The colour varies from a light yellow to a reddish-brown which may be partially surrounded by fat. In rare

cases, the glands can appear orange or greenish-yellow and in children a salmon-pink colour is often noted.¹⁸ The yellow tan is attributable to a higher fat content and the salmon-pink colour observed in children is due to a lower fat content. The glands are usually **soft and pliable and with a smooth surface**. The cut surface of a gland appears vascular and its capsule is often visible.

Other structures in close proximity to the parathyroid glands must be identified by the surgeon. Fat lobules, lymph nodes, thyroid nodules and the tips of the upper cornua of the thymus gland can complicate the identification of the parathyroid glands. **The surface of a parathyroid gland is usually not as shiny as that of a fat lobule, but is often surrounded by a fat lobule. Parathyroid tissue is**

Table 29.1 An aid to identify a parathyroid gland. Distinguishing features between tissues found in close proximity to the parathyroid glands.

	Parathyroid gland	Lymph node	Fat lobule	Thyroid nodule
Colour	Yellow or reddish-brown Blue if stained with Methylene blue	More translucent appearance than parathyroid tissue	Yellow	Reddish
Consistency	Soft Mobile ('wobbles')	Hard	Soft	Hard
Form (appearance)	Distinct edge/capsule (Like a 'baby spleen')	Indistinct Less well demarcated from surrounding fat		Not separable from thyroid gland
Texture	Fine texture/homogenous	Not homogenous		Less homogenous
Vascularity	Minute blood vessels in hilus of gland/vascular	Less vascular	Less vascular	Less vascular

denser than fat and sinks in normal saline, but the latter floats. This helps to differentiate the two types of tissue.¹⁴ A specific finding when parathyroid tissue is cut is that the cut surface oozes, testifying to its marked vascularity and therefore confirming identification. Its appearance is similar to that of other vascular organs, such as the liver or spleen. Whereas fat and lymph nodes are not as vascular as parathyroid tissue when cut, they tend to lose their shape and the thymus gland bleeds very little. However, the definitive identification is performed by a frozen section examination. Identifiable features of parathyroid glands are outlined in Table 29.1.

Anatomical location

Great variation exists in the final anatomical location of the parathyroid glands. This is attributed to the complex migratory pathways and embryological development with other glandular tissue, the thymus and thyroid glands.

The superior parathyroid gland is more constant in position compared to the inferior parathyroid gland. It lies posterior to the corresponding upper half of the thyroid lobe, either at the cricothyroid junction or adjacent to the upper pole at a point at which the inferior thyroid artery enters the substance of the thyroid gland.¹⁴ This corresponds to the level of the posterior ring of the cricoid cartilage. This finding was observed in 99 percent of cases dissected by Wang (77 percent at the cricothyroidal junction and 22 percent behind the upper pole of thyroid gland), 92 percent of cases dissected by Gilmour and 80 percent of cases dissected by Akerström.^{4, 11, 14} Therefore, this constant anatomical location in the majority of cases provides a useful landmark for the superior glands which are in a circumscribed area above the intersection between the inferior thyroid artery and the recurrent laryngeal nerve. In Wang's study, 22 percent of the glands behind the upper pole of the thyroid were subcapsular (below the thyroid capsule). They were always mobile and demonstrated a fine vascular pedicle,

which originated from the thyroid gland. This is useful in distinguishing these glands from thyroid nodules at operation.

Akerström observed that the glands were often hidden by the connective tissue binding the posterior edge of the thyroid lobe to the pharynx, but the glands remained mobile. Occasionally, the glands were immobile and attached to the thyroid capsule.⁴ In 4 percent of cases the superior gland was located more inferiorly, obscured by the inferior thyroid artery, recurrent laryngeal nerve or a protrusion of the thyroid gland (tubercle of Zuckerkandl).^{4, 11} More unusual sites have been documented, 2 percent of cases at the upper thyroid pole and 1 percent above the upper thyroid pole. Other ectopic sites found were more posterior in the neck in the retro-pharyngeal or retro-oesophageal space (1 percent of cases).⁴ One cause for failure in parathyroid exploration is that the surgeon does not explore the neck far enough posteriorly. If the initial exploration was performed by a less experienced surgeon, re-exploration is relatively simple as this posterior field will not have been entered. Indeed, at post-mortem, experienced pathologists choose to look for the parathyroid glands via a posterior approach starting at the vertebral column and extending anteriorly. This point is vital to the understanding of parathyroid exploration.

The inferior parathyroid glands are more widely distributed. In 81 percent of glands dissected by Wang, and 70 percent in Gilmour's series, the inferior glands were distributed evenly between the lower pole of the thyroid and the thymus gland.^{11, 14} Akerström found more than half of the inferior glands were located either inferior, posterior or lateral to the lower pole of the thyroid. Some of the lower glands were situated anteriorly on the lower thyroid lobe (17 percent of cases). Other locations of the inferior glands are inferior to the thyroid in close association with the thyrothymic ligament (fibrous tissue connecting the inferior pole of the thyroid to the superior aspect of the thymus) or within the cervical part of the thymus (26 percent of cases).⁴

The majority of superior mediastinal parathyroid glands can be explored successfully through the neck (98 percent of cases) and it is rare not to be able to reach a thymic parathyroid gland in this way.

Clearly, in the operation of total parathyroidectomy in cases of renal failure, it would be important in this situation to thoroughly explore the superior mediastinum and expose the thymus. This can nearly always be achieved via the cervical route. Sternal split is usually only required in cases where there has been previous retrosternal surgery such as in cases of coronary artery grafting, previous exploration for parathyroid glands in this area or a rare occurrence of ectopic parathyroid tissue in the aortopulmonary window. Rarer sites for an inferior parathyroid gland include an area extending from the carotid bifurcation (due to failure of descent embryologically) to the anterior and posterior mediastinum.^{4, 11} Failure to localize parathyroid tissue can also be due to its location within the carotid sheath, which sometimes needs to be explored. Inferior glands which fail to descend are located superiorly to the superior parathyroid glands and usually have remnants of thymic tissue surrounding them which facilitates their identification. Postero-inferior embryonic displacement can result in inferior glands being placed along the recurrent laryngeal nerve and along the lateral border of the oesophagus.¹⁹ Theoretically, however, parathyroid glands can be ectopically located anywhere from the base of the skull to the diaphragm, but in practical terms such cases are rare and usually fit into the previously described scheme for locating parathyroid glands. **Figure 29.4b** illustrates the potential ectopic sites for the parathyroid glands.

Normal parathyroid glands in ectopic locations receive their blood supply from local vessels, for example, the thymic or internal thoracic arteries. Usually, the inferior glands are obscured by fatty or vascular tissue, or lie within the fibrous sheath of the thyroid gland, which makes identification difficult.

Symmetry in position of the superior glands has been documented in 80 percent of cases, in inferior glands in 70 percent of cases and for all four glands 60 percent of cases.⁴ Asymmetrical locations of the parathyroid glands have been demonstrated. Three glands were located within the thyroid region and a fourth gland from either side was located within the thymus (13 percent of cases); on one side the superior and inferior glands were located above and below the inferior thyroid artery and recurrent laryngeal nerve intersection, respectively, and on the other side both superior and inferior glands were located below (5 percent cases) or above (2 percent cases) the intersection.⁴

Arterial blood supply

The principal blood supply to the parathyroid glands is from specific ascending glandular branches from par-enchymal, muscular or oesophageal branches of the

inferior thyroid artery.²⁰ The inferior thyroid artery is a branch of the thyrocervical trunk, which arises from the first part of the subclavian artery.²¹ The artery ascends anterior to the medial border of scalenus anterior and turns medially at the level of the sixth cervical vertebra. At this point, it descends on *longus colli* to the lower border of the thyroid gland. The superior thyroid artery, a branch of the external carotid artery may supply the superior parathyroid gland, but more commonly it receives an independent direct blood supply from the inferior thyroid artery.²² However, there is considerable controversy about the arterial supply to the superior parathyroid glands. Injected contrast material into the superior thyroid artery of cadavers demonstrated that it supplied the superior parathyroid gland in 98 percent of cases. A distinct anastomosis between the superior and inferior thyroid arteries was seen in 45 percent of cases.²³ Laser Doppler flowmetry has shown that the blood supply to the parathyroid glands is not as dependent upon the inferior thyroid artery as previously suggested.²⁴ Occlusion of either the inferior or superior thyroid artery decreased blood flow to the parathyroid glands by approximately one-third.

A single artery usually supplies each gland, dividing into several branches before entering the glandular tissue, although sometimes, two or three vessels may supply a gland. The *thyroidea ima* artery and other accessory vessels may contribute to the blood supply but are of less importance. Ectopic parathyroid tissue receives its blood supply locally, as mentioned earlier. Despite vascular anastomoses existing between the thyroid vessels, injury to the vascular supply to the parathyroid gland can result in infarction and necrosis, an important point to note at operation. There have also been reported cases of spontaneous infarction of the parathyroid glands in patients with hypercalcaemia and subsequent resolution.^{25, 26, 27}

Venous drainage

The parathyroid gland veins drain via the thyroid venous plexus. The superior and middle thyroid veins drain the upper and central parts of the ipsilateral thyroid and parathyroid glands in that region. The superior thyroid veins are relatively constant in position and always drain into the internal jugular veins, but can communicate with the facial venous system superiorly. The middle thyroid vein's point of entry into the internal jugular vein is variable. The inferior thyroid veins are more variable in position and usually drain into the left brachiocephalic vein.^{28, 29} Dunlop showed that the left and right inferior thyroid veins fuse to form a common trunk which drains into the proximal portion of the left brachiocephalic vein in 60 percent of patients. Drainage into the right and distal segment of the left brachiocephalic vein was also documented. In some patients the inferior thyroid veins drained the mediastinum, communicating with the thymic

vein. Monchik³⁰ performed 32 autopsies and demonstrated that the inferior thyroid veins drained separately into the left brachiocephalic vein (25 percent of cases) or formed a common trunk (47 percent of cases). Occasionally, the inferior thyroid venous trunk drained directly into the internal jugular vein. Each parathyroid gland tends to drain ipsilaterally and inferiorly, but contralateral drainage can occur. This results from anastomoses posteriorly with the vertebral venous plexus and anteriorly with the anterior jugular veins, which drain via the transverse cervical vein into the subclavian vein.

Innervation

The nerve supply to the human parathyroid glands is principally adrenergic from the sympathetic system.^{31, 32} Sympathetic fibres reach the glands from the superior and middle cervical sympathetic ganglia or via the perivascular plexus of the thyroid gland. The nerves are vasomotor, but not secretomotor, with gland activity controlled by changes in plasma calcium levels.³³ Further evidence for this is that transplanted parathyroid glands function normally.

Microscopic appearance

The parathyroid gland has a thin connective tissue capsule and septae which divide it into lobules. Vascular mesenchyme grows into nodules on the dorsal aspect of the pharyngeal pouches to form a rich capillary network in the parathyroid glands. Chief cells, or principal cells, synthesize PTH and are the predominant cell type in the parathyroid gland of children. There are three types of chief cells, dependent upon the depth of cytoplasmic staining visible on light microscopy, named light, dark and clear cells. The chief cells are organized into columns surrounded by sinusoidal capillaries responsible for transporting PTH from the gland. Chief cells in humans can be divided into active and inactive cells, the latter outnumbering the former by three to one.

A second cell type, the oxyphil cell, becomes apparent before puberty and increases in number with age. Oxyphil (eosinophilic) cells are not thought by some to be involved in the secretion of PTH, but have high concentrations of mitochondria. Rare cases of hyperparathyroidism have been documented with only oxyphil cells present in the excised glands. Excess hormone production stopped when these glands were removed, hence, their probable role in PTH secretion, though the exact role of these cells remains to be elucidated.³⁴ A third transitional cell has also been described though its exact function is unknown.³⁵ Connective tissue starts to increase in the glands of young adults. With advancing age the number of fat cells increases and may occupy 60–70 percent of the gland in an elderly adult, with associated decrease in the functional mass of chief cells.

SURGICAL VIEWPOINT

The surgical approach to the parathyroid glands should involve the following important points.

- Is this a normal parathyroid gland? Knowledge of the variations in appearance will aid the surgeon to identify normal parathyroid tissue. Tissue located in the region of the parathyroid glands may be mistaken for parathyroid tissue, especially lymph nodes, fat lobules and thyroid nodules.
- How many parathyroid glands are there? This is variable but it is uncommon for either less than three or more than five glands to be found.
- Where are the parathyroid glands located and what are the possible locations of an aberrant parathyroid gland? Bearing in mind the embryological development and due to the variable extent of their migratory pathways, the surgeon should have a systematic approach to explore the anatomical regions in which the parathyroid glands are likely to be found. The superior parathyroid glands are more constant in their location than the inferior glands. A missing parathyroid gland may be located at an ectopic site more often than the patient having only three glands.

PHYSIOLOGY OF PARATHYROID GLANDS

Calcium homeostasis is mediated by the complex interactions of PTH, an active metabolite of vitamin D, 1,25-dihydroxyvitamin D₃ (1,25-(OH)₂D₃) and calcitonin. The average human contains 800–1000 g of calcium, of which 99 percent is skeletal and a small fraction is extracellular. Fifty percent of plasma calcium exists in its free (ionized) form, which is metabolically active and under tight hormonal regulation. The remainder is bound to albumin, and small amounts are bound to pyruvate, citrate and lactate.

PTH

PTH is secreted by chief cells of the parathyroid gland and is essential for the maintenance of life in humans. Essential functions reliant upon tight regulation of serum calcium levels include neural transmission, muscle contraction (and relaxation), exocrine secretion, blood clotting and cellular adhesion. Chief cells can synthesize large amounts and rapidly secrete stored PTH, replicate if chronically stimulated, giving short-, medium- and long-term control of serum calcium levels. PTH is a polypeptide, 84 amino acids long, derived from a precursor molecule of 115 amino acid residues, pre-proPTH. Pre-proPTH has a 25 residue 'pre' or signal sequence which, if mutated, results in hypoparathyroidism and a six residue 'pro' sequence with

an unknown role.^{36, 37} Pre-proPTH is initially cleaved to proPTH (90 amino acids) which ultimately loses six base residues to form PTH. The hormone is cleaved into two major fragments in chief cells and Kuppfer cells of the liver. The biologically active fragment is PTH-(1-34).

The parathyroid glands can react within seconds to secrete PTH, being controlled by circulating levels of ionized calcium. Calcimimetic compounds inhibit PTH secretion in humans.³⁸ Catecholamines, magnesium and other stimuli can also affect PTH secretion.³⁹ Calcium-sensing receptors on parathyroid cells determine the extracellular level of serum calcium, controlling PTH secretion. This calcium-sensing receptor is a typical seven-spanning membrane G protein-coupled receptor.^{40, 41, 42} Binding of calcium to the receptor causes a conformational change which lowers intracellular cyclic AMP levels and decreases PTH secretion. The dose-response curve for PTH responding to serum calcium levels is sigmoidal. The minimal secretory rate is low but not zero, with the maximal secretory rate representing parathyroid gland reserve. A steady-state occurs lower on the dose-response curve which means the parathyroid gland responds more efficiently to hypocalcaemia than to hypercalcaemia.⁴³

PTH blood levels are regulated on a minute to minute basis, but over a longer time period PTH gene expression is regulated.⁴⁴ Vitamin D₃ has no effect on PTH secretion *per se* but decreases PTH gene expression.⁴⁵ Regulation of PTH gene expression is relevant in patients with renal failure, as low calcium and 1,25-(OH)₂D₃ levels and uraemic toxins alter calcium homeostasis. Treatment with vitamin D₃ and calcium will increase calcium absorption inhibiting PTH secretion by the parathyroid glands.

Parathyroid cells replicate little in adulthood, but can increase dramatically in number secondary to hypocalcaemia, low levels of vitamin D₃ and neoplasia. Calcium inhibits PTH cell proliferation. An increased cell number secondary to hypocalcaemia is a slow response, but appears to be irreversible, as after renal transplantation persistent hyperparathyroidism can be problematic.

The half-life of PTH is 2 minutes, with 70 percent metabolized in the liver and 20 percent in the kidneys. Less than 1 percent of secreted PTH reaches its target organs.⁴⁶ Therefore, PTH blood levels are principally related to the rate of secretion.

Actions of parathyroid hormone

PTH acts on a number of target tissues, mostly increasing the circulating levels of calcium and decreasing phosphate (PO₄³⁻). The receptor for PTH has been cloned.⁴⁷ The receptor is found in the kidney and osteoblasts but not osteoclasts or in the intestine.

PTH plays an important role in the kidney.⁴⁸ Almost all calcium in the glomerular filtrate of the kidney is reabsorbed, 65 percent in the proximal convoluted tubule, 20 percent in the thick ascending limb of the loop of

Henle and 10 percent in the distal convoluted tubule. Some reabsorption in the thick ascending limb of the loop of Henle and the distal convoluted tubule is PTH dependent, thus helping to increase serum calcium levels. PO₄³⁻ reabsorption occurs in the proximal and distal convoluted tubules and is inhibited by PTH, thus decreasing serum PO₄³⁻.

PTH stimulates 1,25-(OH)₂D₃ synthesis in the proximal tubules by activating 25-hydroxyvitamin D-1 α -hydroxylase (25-OH-D₃-1 α -OHase) and decreases renal 24-hydroxylase activity, the major enzyme involved in the destruction of vitamin D.^{49, 50} PTH increases bone resorption by increasing the number and activity of osteoclasts. Despite this relationship, isolated mature osteoclasts cannot respond to PTH, though when cultured with osteoblasts they do so.^{51, 52} The mechanism of bone resorption is dependent upon both cell types interacting closely.

Vitamin D

Exposure to ultraviolet irradiation converts the cutaneous precursor of vitamin D, 7-dehydrocholesterol, to vitamin D₃. The degree of skin pigmentation regulates the conversion by influencing the penetration of ultraviolet light. An important source of vitamin D, if exposure to sunlight is limited, is from dietary sources.

Metabolites of vitamin D are fat-soluble compounds which circulate bound to vitamin D-binding protein, and some to albumin. A small fraction of circulating vitamin D is free. Vitamin D is transported to the liver where it is hydroxylated by cytochrome P450 enzyme to form 25-OH-D₃, the major circulating metabolite but which functionally is weak acting. Further hydroxylation occurs in the proximal convoluted tubules of the kidney to form 1,25-(OH)₂D₃, the main active metabolite. The half-life of 1,25-(OH)₂D₃ is six to eight hours.

PTH and low PO₄³⁻ levels regulate this second crucial hydroxylation step. Calcitonin, 1,25-(OH)₂D₃ and calcium decrease the activity of 1 α -hydroxylase activity.⁵³ Animal work has shown that other hormones, including oestrogen, growth hormone and prolactin, increase 1 α -hydroxylase activity but the significance of this in humans has not been shown.

1,25-(OH)₂D₃ binds to a nuclear receptor and forms a heterodimeric complex with the retinoid-X receptor. This upregulates target genes that control 1,25-(OH)₂D₃ RNA transcription.⁵⁴

The vitamin D-receptor is expressed by most tissues and regulates cellular differentiation and function in many cell types. Probably the most important physiological function is the regulation of intestinal calcium transport. Calcium is absorbed in the intestine by three pathways: transcellular, vesicular and paracellular transport. The transcellular and vesicular pathways are 1,25-(OH)₂D₃ dependent. The role of 1,25-(OH)₂D₃ in the regulation of paracellular transport remains controversial.

$1,25-(\text{OH})_2\text{D}_3$ activates osteoblasts which in turn activate osteoclastic-mediated bone resorption. This increases the transport of calcium from the skeletal system to the plasma. Vitamin D-deficient animals have abundant calcium in their bones but cannot mobilize calcium in response to PTH unless $1,25-(\text{OH})_2\text{D}_3$ is administered.⁵⁵ Similarly, parathyroidectomized animals cannot mobilize calcium in response to $1,25-(\text{OH})_2\text{D}_3$ unless PTH is administered. Both PTH and $1,25-(\text{OH})_2\text{D}_3$ are required *in vivo*.

$1,25-(\text{OH})_2\text{D}_3$ and PTH function in concert in the distal convoluted tubule of the kidney, controlling the reabsorption of the last 1 percent of filtered calcium. This small amount of calcium may be crucial in the fine balance necessary to regulate calcium levels and by further inhibiting PTH secretion by the parathyroid gland.

Parathyroid hormone-related protein

Parathyroid hormone-related protein (PTHrP) was initially discovered to be secreted by some tumour cells contributing to the hypercalcaemia of malignancy. Unlike PTH, it is made by a variety of normal tissues but has little role to play in the normal regulation of calcium levels. PTHrP has a similar structure to PTH and can stimulate PTH receptors as a result. Fortunately, however, PTHrP is not measured by a standard PTH assay, therefore a patient with possible hyperparathyroidism and a raised PTH level suggests primary hyperparathyroidism. PTHrP functions as a hormone, acting on the kidney and bone elevating serum calcium levels.⁵⁶ PTHrP acts as a calcitropic hormone during foetal life and lactation, which may be involved in the regulation of calcium levels in breast milk.⁵⁷ It is also secreted by a number of normal human tissues, such as skin and hair, and may regulate cell proliferation and differentiation.⁵⁸

Calcitonin

The role of calcitonin in the regulation of human calcium levels is uncertain. It is secreted by the C cells of the thyroid gland and, as mentioned previously, has close embryological origins from the neural crest as the ultimobranchial bodies associated with the development of the superior parathyroid gland.

Calcitonin is a 32 amino acid polypeptide. The calcium-sensing receptor found on parathyroid cells is also found on C cells, and may regulate the release of calcitonin as well as PTH.⁵⁹ Somatostatin secreted by C cells inhibits calcitonin release, and $1,25-(\text{OH})_2\text{D}_3$ decreases calcitonin mRNA levels.

Calcitonin impairs osteoclast-mediated bone resorption, but its physiological role in humans is unknown.⁶⁰ Long-term administration of exogenous calcitonin has resulted in no physiological abnormalities.⁶¹

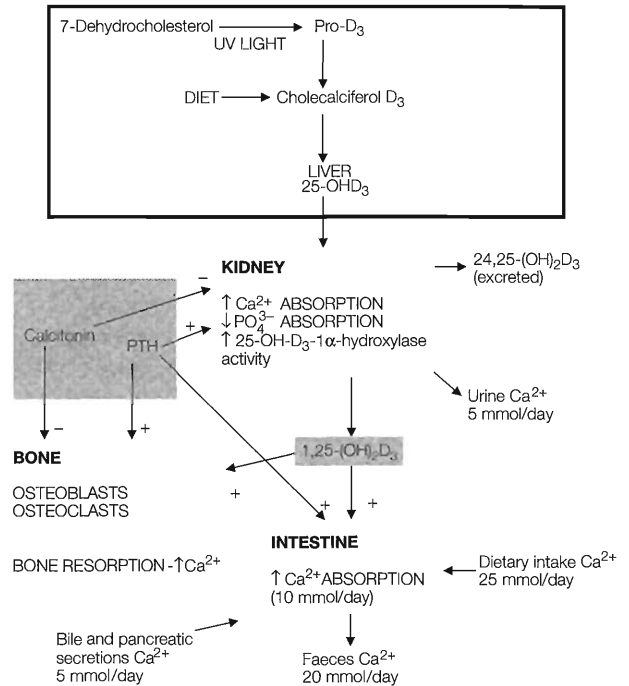

Figure 29.5 Endocrinology of calcium homeostasis. Close interaction between PTH, $1,25-(\text{OH})_2\text{D}_3$ and the kidneys, intestine and skeleton regulating serum calcium levels.

Summary of calcium homeostasis

Serum calcium regulation is controlled within a narrow range by the close interaction of PTH and $1,25-(\text{OH})_2\text{D}_3$. Serum calcium levels regulate hormone secretion and the hormones regulate the production of each other (Figure 29.5).

Low serum calcium levels stimulate the parathyroid gland to secrete PTH, which augments $1,25-(\text{OH})_2\text{D}_3$ synthesis by the proximal renal tubules. This increases the renal reabsorption of calcium. $1,25-(\text{OH})_2\text{D}_3$ also increases the efficiency of intestinal calcium absorption by enterocytes. The combined action of PTH and $1,25-(\text{OH})_2\text{D}_3$ increases serum calcium by inducing osteoclast-mediated bone resorption.

Minimal elevation of serum calcium levels reduces PTH secretion by the parathyroid glands to a minimal amount. The role of calcitonin in humans may inhibit osteoclast-mediated bone resorption to increase osteoblast numbers and decrease osteoclasts.

KEY POINTS

- The inferior parathyroid gland is derived from the third pharyngeal pouch and the superior parathyroid gland from the fourth pharyngeal pouch.
- Embryological descent of the parathyroid glands follows the thyro-thymic axis.

- Usual sites of the parathyroid glands are: superior, above inferior thyroid artery and behind recurrent laryngeal nerve; inferior, below inferior thyroid artery and in front of recurrent laryngeal nerve.
- The inferior parathyroid gland is more variable in position than the superior parathyroid gland.
- A thorough understanding of the embryological development of the parathyroid glands can aid the surgeon when performing a systematic search to localize aberrant parathyroid tissue.
- It is uncommon to find patients with fewer than three or more than five parathyroid glands.
- PTH levels are regulated on a minute to minute basis with a plasma half-life of 2 minutes.
- PTH stimulates bone resorption and 1,25-(OH)₂D₃ synthesis in the proximal tubules of the kidney which increases serum calcium levels.
- 1,25-(OH)₂D₃ increases calcium absorption from the kidney and also increases bone resorption.
- Bone resorption is dependent upon close interaction between osteoblasts and osteoclasts.
- The exact role of calcitonin in the regulation of human calcium levels remains to be elucidated. It may inhibit osteoclast-mediated bone resorption.

SEARCH STRATEGY

The data in this chapter are based on a Medline search using the key words parathyroid glands, parathyroid hormone/analysis, radionuclide imaging, sestamibi, ultrasonography, magnetic resonance imaging, tomography/x-ray computed. These were limited to human studies published in the English language.

NORMAL OR APPROPRIATE PARATHYROID FUNCTION

The role of the parathyroid glands is to maintain a level of extracellular and intracellular fluid calcium, magnesium and phosphate which is compatible with normal cellular and neuromuscular function. When evaluating parathyroid function, it is critical to understand the difference between a 'normal' level of parathyroid hormone (PTH) which lies within the age and sex specific reference range and one which is 'appropriate'. For example, after parathyroidectomy for hyperparathyroidism, the concentration of PTH post-operatively may approach the preoperative level as the gland attempts to maintain a normal ECF calcium in the face of a relative excess of bone formation (hungry bone syndrome). Equally, a normal serum PTH concentration in the presence of hypercalcaemia is inappropriate and indicates the presence of primary hyperparathyroidism. As in many other areas of medicine, normal organ function cannot be defined by a single parameter but by a combination of measurements which indicate whether function is appropriate to the needs of homeostasis and can therefore be regarded as 'normal'.

The tools at our disposal include routine measurements of serum and urine calcium, phosphate, magnesium and sodium together with standard tests of renal and hepatic function. Recent development of the two-site immunoassays for 'intact' PTH avoid the confusion caused by circulating, but biologically inactive, peptides while, on occasion, direct stimulatory tests are needed to identify glandular or end organ resistance. However, most errors in the diagnosis of disorders of mineral metabolism are due to poor attention to detail in the history and examination, rather than incorrect interpretation of laboratory data.

ROUTINE SERUM AND URINE BIOCHEMISTRY

Calcium

METHODOLOGY

Total serum calcium comprises the protein bound (40 percent), ionized (48 percent) and the complexed (12 percent) fractions, and most clinical chemistry laboratories

will correct the serum concentration for the prevailing level of serum albumin which accounts for 90 percent of the protein binding (with the remainder complexed to globulin).¹ If this is not carried out routinely, a simple correction factor is to add (or subtract) 0.2 mmol/L for every G/L by which the albumin falls below (or exceeds) 40 G/L.

It is the ionized serum calcium which regulates all physiological events but measurements require more care since values vary between methods and type of sample (serum, plasma or heparinized whole blood) which must be collected anaerobically to avoid altered calcium binding due to *ex vivo* changes in pH. Although ionized measurements are seldom used in routine clinical practice, they are of value in profound hypoalbuminaemic states, acid-base disturbances and after massive (citrate) blood transfusion where the use of ion selective electrodes has made this methodology more generally available.

TECHNICAL FACTORS

Serum protein concentration rises with the erect posture which seems to be the major cause of the diurnal variation in total, but not protein corrected, calcium. Serum calcium, unlike phosphate, is little affected by food but may show significant variation in hypoparathyroid patients treated with calcium and vitamin D supplements. The normal reference range for calcium is 2.20–2.60 mmol/L and this can be converted to mg/dL by multiplying by four.

INTERPRETATION

The common causes of hypocalcaemia and hypercalcaemia are set out in Table 30.1 together with major clinical and biochemical characteristics which allow their separation.

Phosphate

METHODOLOGY

The importance of the measurement of the plasma phosphate is that it can be used as an indirect (but rapidly available) assessment of parathyroid function since it will be low in hyperparathyroidism and high in hypoparathyroidism. Although hypophosphataemia is a feature of hyperparathyroidism, the plasma phosphate is of much less value in the differentiation of the various causes of hypercalcaemia. The level of plasma phosphate rises after the intake of food and has the greatest discriminatory value when measured during fasting. Plasma levels also rise as renal function deteriorates since less phosphate will be filtered by the glomerulus.

TECHNICAL FACTORS

In nonfasting patients, and those with renal impairment, a random plasma phosphate is unreliable and it is necessary to calculate the setting of renal tubular phosphate reabsorption (TmP/GFR). This requires a simultaneous serum and urine sample measured for phosphate and creatinine from which the clearance of phosphate to creatinine can be calculated from:

$$\frac{C_{\text{phosphate}}}{C_{\text{creatinine}}} = \frac{U_p \times [\text{Creatinine}]}{U_{\text{creatinine}} \times [\text{PO}_4]}$$

and TmP/GFR read off from a nomogram.²

Phosphate moves into cells in response to respiratory alkalosis, the intravenous infusion of glucose, insulin or an increase in adrenaline. Delay in separation of samples or *ex vivo* haemolysis can falsely elevate plasma levels. The normal reference range for plasma phosphate, measured

Table 30.1 Causes of hypocalcaemia and hypercalcaemia.

	Cause	Diagnostic features
Hypocalcaemia	Hypoparathyroidism	Carpopedal spasm, paraesthesiae, fits Abnormal body habitus (pseudohypoparathyroidism) ↑PO ₄ ↓PTH (↑PTH in pseudohypoparathyroidism)

	Sarcoidosis	Erythema nodosum, hilar adenopathy (CXR) ↓PTH ± ↑creatinine ± ↑liver function Steroid responsive hypercalcaemia

Table 30.2 Causes of hypophosphataemia and hyperphosphataemia.

	Cause	Diagnostic features
Hypophosphataemia	Hyperparathyroidism	Primary: 'stones bones abdominal groans' Secondary: vitamin D deficiency/osteomalacia
	Malignancy	Clinical features of primary tumour ↑Ca ↓PTH ± ↑creatinine ± ↑liver function
	Hypophosphataemic osteomalacia	Short stature, no proximal myopathy Normal Ca PTH ± ↑alkaline phosphatase
Hyperphosphataemia	Hypoparathyroidism	Idiopathic: carpopedal spasm, paraesthesiae, fits Pseudohypoparathyroidism (appearance)
	Renal failure	↓Ca ↑PTH ↑creatinine ± renal bone disease

by automated spectrophotometry, is 0.8–1.4 mmol/L and can be converted to mg/dL by multiplying by 3.1.

INTERPRETATION

The common causes of hypophosphataemia and hyperphosphataemia are set out in **Table 30.2** together with major clinical and biochemical characteristics which allow their separation.

Magnesium

METHODOLOGY

Serum magnesium is also regulated by PTH but unlike calcium, where the stimulus is progressive, the initial increase in PTH which develops as serum magnesium falls is replaced by progressive functional hypoparathyroidism. This makes it important to measure serum magnesium in all hypocalcaemic and hypoparathyroid patients. Like calcium, magnesium in serum is present in an ionized (55 percent), protein bound (30 percent) and complexed (15 percent) form but correction factors are not available causing uncertainty in the interpretation of serum levels in the presence of hypoalbuminaemia. The normal serum concentration, usually measured by automated spectrophotometry, is 0.7–1.0 mmol/L and can be converted to mg/dL by multiplying by 2.4.

TECHNICAL FACTORS

Magnesium is a predominantly intracellular ion and serum concentrations are a poor indicator of magnesium status which is best assessed by a magnesium tolerance test which measures the retention after an intravenous load (0.1 mmol elemental Mg²⁺/Kg body weight) in 50 mL 5 percent dextrose over four hours. This correlates well with both skeletal muscle content and Mg balance studies³ in that magnesium-replete individuals excrete > 50 percent of the load within 24 hours while those who

are deplete retain > 50 percent of the dose; probable deficiency is indicated by an intermediate retention of 25–50 percent.

INTERPRETATION

The common causes of hypomagnesaemia and hypermagnesaemia are set out in **Table 30.3** together with major clinical and biochemical characteristics which allow their separation. Because magnesium deficiency is usually secondary to some other disease, the clinical and biochemical picture is usually dominated by the primary cause. Important clues to the presence of magnesium depletion are the presence of hypokalaemia and hypocalcaemia. Magnesium is needed for the effective tubular reabsorption of potassium, and hypokalaemia in this situation may be resistant to the administration of potassium supplements because of the renal leak. In addition, as magnesium depletion progresses, the initial stimulation of PTH secretion is replaced by progressive functional hypoparathyroidism and the development of hypocalcaemia.

Hypermagnesaemia is an uncommon problem and is usually due to inappropriate rates of infusion particularly where there is renal impairment. [****]

Table 30.3 Causes of hypomagnesaemia and hypermagnesaemia.

Cause	Diagnostic features
Gastrointestinal loss	Malabsorption, prolonged nasogastric suction Acute/chronic diarrhoea
Renal tubular disease	Diuretics, cisplatin, aminoglycosides Inherited defects, chronic renal disease Post-renal transplantation
Alcoholism	
Parathyroid failure or resistance	

Best clinical practice

- ✓ Parathyroid function needs to be assessed in conjunction with the prevailing levels of calcium, phosphate and magnesium.
- ✓ Serum calcium must be corrected for serum albumin but need not be measured fasting.
- ✓ Phosphate is elevated by food and renal failure and in their presence it is necessary to calculate Tmp/GFR.
- ✓ Magnesium is predominantly intracellular ion and depletion is best assessed from the retention after an intravenous load.

PTH

PTH is secreted as a 1–84 amino acid peptide with a half-life of less than five minutes, but is cleaved both within the parathyroid gland and in the peripheral tissues, such as the liver, to shorter carboxy-terminal peptides which have much longer half-lives. These fragments, together with a larger 7–84 peptide, are eliminated from the serum mainly by glomerular filtration and subsequent tubular degradation.⁴ As a consequence, their circulating concentrations are relatively high relative to the biologically active intact hormone.

Current PTH assays in clinical use are based on a two-site immunoradiometric assay (IRMA) using antibodies to the 1–34 region of PTH with another reacting with the 39–84 C-terminal sequence.⁵ This technique does not measure biologically inactive C-terminal fragments, is sensitive enough to detect PTH in normal subjects and can distinguish them from patients in whom PTH is suppressed. It completely separates hypercalcaemic patients with hyperparathyroidism from those with malignancy. The assay has precision over a wide range of PTH concentrations and, with a turnaround time of 24 hours, it has proved durable in clinical practice. However, it is clear that as well as measuring 1–84 PTH it also cross-reacts with the 7–84 peptide (N-terminal truncated PTH), and even the more recently developed ‘specific’ 1–84 assays include a 10–20 percent contribution from 7–84 PTH in normal subjects or patients with primary hyperparathyroidism.⁶ This proportion may rise to 35 percent in chronic renal failure but even here there is a close correlation between assays detecting only 1–84 PTH and those that measure fragments as well as intact hormone.⁷ The clinical significance of the truncated peptide is uncertain but there is experimental evidence that it may act as an endogenous inhibitor to PTH.⁸ At present, there is insufficient evidence that the differences between the assays that measure PTH (1–84) alone and those that also measure the N-terminal truncated peptide influence clinical management and this is also true for most cases of chronic renal failure.⁹ [***]

PTH measurements in clinical practice

The major indications for PTH measurement are outlined below.

- **Diagnosis of the causes of hypercalcaemia (Table 30.4) and hypocalcaemia (Table 30.5).** The major distinguishing features of these conditions have already been outlined in the sections on calcium, phosphate and magnesium.
- **Guide to therapeutic strategies:**
 - Management of renal bone disease. It is important to be able to separate adynamic and hyperparathyroid bone disease since their management is different. Adynamic bone disease may be associated with oversuppression of parathyroid function and this is an important constraint to the use of active vitamin D metabolites or anti-resorptive drugs.
 - Adjustment of phosphate therapy in hypophosphataemic osteomalacia. Phosphate supplements are an essential component of treatment but lead to calcium malabsorption,

Table 30.4 PTH concentration in hypercalcaemia.

Concentration	Effect
High	Primary or tertiary hyperparathyroidism Familial hypocalciuric hyperparathyroidism Lithium
Normal	Primary hyperparathyroidism Familial hypocalciuric hyperparathyroidism Lithium
Low	Malignancy Vitamin D intoxication Sarcoidosis Immobilization Milk-alkali syndrome Addison's disease

Table 30.5 PTH concentration in hypocalcaemia.

Concentration	Effect
High	Vitamin D deficiency Pseudohypoparathyroidism Acute pancreatitis 'Hungry bone syndrome' Post-parathyroidectomy Sclerotic metastases Acute inhibition of bone resorption
Normal	Functional hypoparathyroidism Spurious hypocalcaemia (hypoalbuminaemia)
Low	Hypoparathyroidism Magnesium deficiency

secondary hyperparathyroidism and worsening of the phosphate leak. This has to be offset by calcitriol therapy where the dose is adjusted to maintain a normal level of PTH.

- Evaluation of vitamin D nutrition in osteoporosis. Many elderly patients with osteoporosis have an inadequate intake of vitamin D which leads to secondary hyperparathyroidism, increased bone turnover and amplification of their age-related or postmenopausal bone loss. This can be corrected by vitamin D supplementation.

End organ resistance to PTH (pseudohypoparathyroidism)

This is an unusual syndrome expressing the combination of biochemical hypoparathyroidism, an unusual body habitus (Albright's hereditary osteodystrophy: short metacarpals, round face, truncal obesity and basal ganglia calcification) with end organ resistance to the action of PTH leading to secondary hyperparathyroidism. Prior to the introduction of the current two-site PTH assay, this syndrome was usually confirmed by demonstrating an impaired serum or urinary cyclic AMP response to exogenous PTH¹⁰ and this still remains the most reliable way of separating the different variants of this rare syndrome.¹¹ In practice, the identification of this condition can be made from a combination of the clinical picture, the biochemical features of hypoparathyroidism (and the absence of vitamin D deficiency) in the presence of an elevated PTH. [****/***]

KEY POINTS

- Assays for 1–84 PTH cross-react to some extent (10–20 percent) with an N-terminal 7–84 truncated peptide, but this may not adversely affect the clinical utility of the measurement.
- Current assays reliably separate hyperparathyroidism from the hypercalcaemia of malignancy.
- PTH measurements are an integral part of the diagnosis and management of most common metabolic bone diseases.

PARATHYROID IMAGING

The major stimulus for the development of parathyroid imaging, with the required sensitivity and specificity, has been the interest in minimally invasive

parathyroidectomy, which is critically dependent on reliable identification of the abnormal gland(s). Two technical options are available.

Dual phase single tracer scintigraphy

This relies on the differential time course of tracer uptake by the thyroid (early at 10 minutes) and parathyroids (late at 120 minutes). The problem is that approximately 30 percent of patients have coincidental thyroid nodules¹² which may have a tracer uptake similar to that of the parathyroid glands (false positive). In contrast, some parathyroid adenomas may show early tracer washout leading to false negative scans, and a comparison of early and late imaging¹³ showed that the former had a higher sensitivity (92 percent) than the latter (74 percent). Another option is to combine scintigraphy with ultrasound to separate thyroid and parathyroid nodules.¹⁴

Sestamibi = methoxyisobutylisonitrile or MIBI

DUAL ISOTOPE SUBTRACTION SCANS

With this method, a tracer which is only taken up by the thyroid is subtracted from the thyroid/parathyroid sestamibi image using data acquisition which can be either sequential or simultaneous. The latter avoids motion artefact but requires separation of the two tracer energies.¹²³I is the optimal thyroid scanning agent but is not available on a daily basis from a generator and ^{99m}Tc is an alternative. Use of ^{99m}Tc pertechnetate may give quite high thyroid activity and may obscure the relatively low uptake from a posteriorly placed parathyroid. This can be overcome by the use of oral potassium perchlorate to wash out the ^{99m}Tc pertechnetate from the thyroid.¹⁵

Choice of tracer

There has also been considerable interest in the choice of tracer for parathyroid imaging. The accuracy of thallium-technetium scanning is dependent on adenoma size¹⁶ and, since it is the small gland that presents the surgical problem, there has been a shift to the use of the more sensitive ^{99m}Tc-sestamibi.^{13, 17} In a meta-analysis of 6331 cases scanned with ^{99m}Tc-sestamibi, there was a sensitivity of 90.7 percent and a specificity of 98.8 percent.¹⁸ [***]

The ability to use the same tracer for multiple imaging techniques has stimulated the use of ^{99m}Tc-tetrofosmin, which can also be used in nuclear cardiology. This tracer is unsuitable for dual phase imaging because of poor differential washout between thyroid and parathyroids, but it can be used with dual isotope subtraction scanning. In a direct comparison of ^{99m}Tc-sestamibi and tetrofosmin it was shown that the early differential uptake by thyroid and parathyroids was poorer with tetrofosmin, but the later uptake was superior to sestamibi.¹⁴

SINGLE PHOTON EMISSION TOMOGRAPHY

Single photon emission tomography (SPET) has the advantage over the planar technique in terms of separation of thyroid and parathyroid images, improved ability to localize ectopic glands, specificity and sensitivity.¹⁴ There have been direct comparisons between planar scanning and SPET which have supported its superiority over both planar dual phase and subtraction techniques¹⁹ although delayed phase SPET may not be optimal.²⁰ If the technique is available, as it may be in some nuclear cardiology departments, then it does have attractions as a routine parathyroid imaging technique. Otherwise, its main application is in the identification of ectopic parathyroid glands or where there has been a failed neck exploration.

ULTRASOUND, CT AND MRI

Local expertise with ultrasound, CT and MRI may determine its use in a particular centre. Ultrasound is widely available but highly dependent on operator skill, with the result that the reported sensitivity of this technique in parathyroid disease ranges from 30 to 90 percent.²¹ Particular limitations of ultrasound are the inability to identify medially situated upper parathyroid glands and those which are intrathyroidal or in the mediastinum. Ultrasound is good for identifying parathyroids behind the thyroid or below the lower poles. Identification of their vascular pedicles by Doppler ultrasound can also help distinguish thyroid and parathyroid adenomas.

CT and MRI find their main role in the localization of mediastinal parathyroid glands. The major limitation with CT is the similar densities of thyroid and parathyroid tissue and, in the neck, MRI may be preferable. Even so, MRI is generally less sensitive and specific than sestamibi scanning.¹⁴

INTRAOPERATIVE GAMMA PROBE LOCALIZATION AND RAPID PTH ASSAY

In difficult cases, a combination of preoperative scintigraphy, intraoperative gamma probe gland localization with measurement of tracer content of removed tissue²² and confirmation by rapid PTH assay may be helpful.²³ In this approach, ^{99m}Tc-sestamibi is administered two to three hours before operation and a hand-held gamma probe is used to localize abnormal parathyroid tissue (> 20 percent above background).²⁴ A requirement is that the preoperative sestamibi scan has shown the presence of an adenoma (approximately 80 percent of cases), although the gamma probe may be useful where there has been a negative scan in reoperative procedures or where there is an ectopic gland.²⁵ While helpful, the gamma probe may not provide unique information which

will not be available from other modalities, such as the preoperative sestamibi scan. The rapid PTH assay with a turnaround time of 15 minutes does provide additional practical information:

- prediction of clinical cure (decrease in intraoperative PTH >50 percent);²⁶
- indicates the probability of multiglandular disease (and the need for a bilateral neck exploration);
- suggests the probability of postoperative hypoparathyroidism and the potential for autografting of removed parathyroid tissue (final PTH below the lower limit of detection).

This approach seems particularly appropriate for specialist centres treating a high proportion of failed or recurrent hyperparathyroidism, but there is no evidence that it is needed for previously untreated primary hyperparathyroidism. [**]

Indications for parathyroid imaging

The need for parathyroid imaging is driven entirely by the interest in limited surgery for hyperparathyroidism. This seems reasonable for a condition which is due to a solitary adenoma in almost 90 percent of patients.¹⁸ Minimally invasive parathyroidectomy offers the prospect of shorter operation times under local anaesthetic as day cases²⁷ with potential cost savings and may follow the trend in other areas by being driven by patient preference. The need here is to identify cases with a single adenoma, since those with hyperplasia, multigland disease or abnormal neck anatomy (goitre, previous neck surgery or irradiation) will need a bilateral operation, which remains the 'gold standard' against which newer approaches are judged. A recent meta-analysis suggested that 87 percent of patients with sporadic primary hyperparathyroidism would be candidates for a unilateral parathyroidectomy.¹⁸ However, while a recent systematic review of minimally invasive parathyroidectomy suggested that it may have an advantage over the bilateral exploration, the confidence intervals were wide and there may have been bias due to rigorous case selection.²⁸

There is general agreement that patients with failed or recurrent hyperparathyroidism require detailed preoperative imaging, and this approach is increasingly being extended to the previously untreated case since localization of the adenoma allows unilateral operation which is of shorter duration. However, the experienced parathyroid surgeon has a better than 90 percent probability of success compared to the 80 percent identification rate of sestamibi and may well find the small gland missed by scanning.²⁹ The conventional bilateral surgical approach of identifying all the parathyroid glands may succeed where scanning may fail if there are asymmetrically enlarged glands and only the largest adenoma is identified. [***]

KEY POINTS

- No single test of parathyroid function is diagnostic.
- Measurement of serum calcium, phosphate, magnesium and PTH are the main tests of function.
- The two-site IRMA for intact PTH is reliable and discriminatory.
- Misdiagnosis of calcium disorders is usually due to lack of attention to history and examination rather than incorrect interpretation of laboratory tests.
- Intraoperative measurement of PTH may facilitate management.
- ^{99m}Tc -sestamibi parathyroid imaging has high sensitivity and specificity. It is increasingly used to identify a solitary adenoma and facilitate unilateral parathyroidectomy.
- Ultrasound, CT and MRI may help in the localization of ectopic glands.

Best clinical practice

- ✓ Dual phase single tracer scintigraphy or dual isotope subtraction scans are the method of choice for the identification of a parathyroid adenoma.
- ✓ ^{99m}Tc -sestamibi scanning has 90 percent sensitivity and almost 99 percent specificity for a solitary parathyroid adenoma.
- ✓ SPET, ultrasound, CT and MRI may have a place where there is local expertise but they are less sensitive and specific.
- ✓ Rapid PTH assays with a turnaround time of 15 minutes provide important additional information during parathyroidectomy.

Deficiencies in current knowledge and areas for future research

- Refinements in the assays for PTH are needed to eliminate cross reactivity with peptide fragments. This would be important in better defining changes in parathyroid function in disease states since this would influence both diagnostic precision and facilitate management. Such assays would need validation over a wide range of disease states including renal failure.
- Although sestamibi scanning is now well established, its use in the management of primary

hyperparathyroidism is dependent on careful case selection to eliminate possible cases of hyperplasia or multiple adenomata. Development of an imaging technique which was able to distinguish multiple parathyroid glands from the normal or adenomatous thyroid would greatly increase the scope of preoperative gland localization.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words parathyroid glands, hyperparathyroidism, hypercalcaemia and parathyroid carcinoma. Further relevant articles were obtained by manual screening of the reference lists of selected papers.

NORMAL PARATHYROID GLANDS

Anatomy

The parathyroid glands are best identified by their relationship to the plane of the recurrent laryngeal nerve: superior glands posterior and inferior glands anterior to this plane. There are four glands in 87 percent of patients, five in 6 percent and six in 0.5 percent, but up to ten have been reported in one individual, which may in fact represent chief-cell hyperplasia. In less than 1 percent of cases only three glands are identified.^{1,2} There is also positional symmetry to the upper parathyroid glands in 80 percent of cases and to the inferior glands in 70 percent of cases.

Embryology

Parathyroid glands are formed during the fifth week of intrauterine life. Superior glands develop from the fourth

pharyngeal pouch and are found at the junction of the upper and middle third of the posterior surface of the thyroid gland, near the cricothyroid junction in 80 percent of cases. The importance of this position is its proximity to the point where the recurrent laryngeal nerve enters the larynx. In 15 percent they are found on the posterior surface of the thyroid, while 3 percent are to be found in retro-oesophageal, retrolaryngeal or retro-pharyngeal positions and, finally, 1 percent lie above the thyroid upper pole.

Inferior glands develop from the third pharyngeal pouch and are closely related to the developing thymus (thyrothymic ligament). The inferior glands take a longer and more variable migration through the neck, with a more widespread final resting position and ectopic glands potentially anywhere from the carotid bifurcation down to the pericardium. The inferior glands are at the lower pole of the thyroid in 50 percent of cases, within the thymus or the thyrothymic ligament in 25 percent, while approximately 10 percent are more lateral and 10 percent lie on or next to the trachea.

Physiology

Parathyroid glands are composed of chief and oxyphil cells, and secrete parathyroid hormone (PTH), which plays a major role in calcium metabolism either by directly acting on the bone or indirectly through vitamin D. Calcium ion homeostasis is maintained by a complex of hormones and different organ systems, controlled by PTH, vitamin D and calcitonin.

PTH

PTH is synthesized and secreted by the chief cells in response to a fall in extracellular calcium concentrations. PTH is secreted in an episodic manner as pre-pro and pro-PTH, before being cleaved into fragments within the chief cells and in the Kupffer cells of the liver. The 1–34 N-terminal fragment is the biologically active form of PTH, which has a half-life of PTH of around five minutes.

Parathyroid and C-cells utilize a calcium sensing receptor (CaR), which senses the level of extracellular calcium to determine the secretion of PTH and calcitonin (see below). PTH acts on target tissues by binding to PTH receptors on the cell surface. Three PTH receptors have been described to date with PTH-1 being the most important mediator of PTH and parathyroid hormone-related peptide (PTHrP) actions on calcium homeostasis.³ In bone, PTH induces bone resorption by indirectly acting on osteoclast cells to increase their number and activity. It acts via the PTH-1 receptor primarily on osteoblasts, which release a cytokine that acts on the osteoclasts.

In the kidney PTH acts via the PTH-1 receptor to decrease calcium excretion by increasing the reabsorption of calcium in the distal convoluted tubule. It also increases phosphate excretion and stimulates production of calcitriol, the active form of 1,25 dihydroxycholecalciferol (vitamin D) in the proximal convoluted tubule. This PTH-induced increase in calcitriol has an effect on the intestine which results in enhanced gut absorption of calcium.

PTHrP

PTHrP closely resembles PTH and is an important mediator regulating the hypercalcaemia of malignancy. It acts via all three PTH receptors, and the PTH-2 receptor will only bind PTHrP. The normal physiological role for PTHrP appears to be in the foetus, where it facilitates placental mineral transport.

VITAMIN D

1,25-dihydroxy-vitamin D is a fat-soluble compound, synthesized in the skin from its precursor 7-dehydro-cholesterol by the action of sunlight, and is also derived

from plant ergosterol in the diet. It is transported to the liver where it is converted to the major circulating metabolite 25-hydroxycholecalciferol. A further hydroxylation to the active form 1,25-dihydroxycholecalciferol takes place in the kidney, under the control of PTH and calcitonin. Vitamin D exerts its action through specific receptors present in the cell nucleus in bone and gut.

CALCITONIN

Calcitonin is a hormone secreted by the parafollicular cells of the thyroid, with a half-life of ten minutes. Calcitonin reduces the serum calcium level by its effect on specific cell surface receptors on osteoclasts and on the proximal convoluted tubules. The exact physiological role of calcitonin remains uncertain however, as patients with high circulating calcitonin levels in medullary carcinoma of the thyroid do not have any disorder of calcium homeostasis.

CALCITONIN GENE-RELATED PEPTIDE

Calcitonin gene-related peptide (CGRP) is the product of the same gene that directs the synthesis of calcitonin, and is found in thyroid, pituitary, pancreas and adrenal medulla. Its exact role is unknown.

OTHER HORMONES

Other hormones that affect calcium metabolism are only important in times of greater calcium need, such as during growth, pregnancy and lactation. These are growth hormone, oestrogens, corticosteroids, thyroxine and insulin. [**/**]

GENETICS OF HYPERPARATHYROIDISM

Most of the parathyroid disorders are due to genetic abnormalities and have a familial tendency. These genetic disorders are due to a defect in either PTH or the PTH receptors producing either hyper or hypoparathyroidism.⁴

Parathyroid tumours are either sporadic or inherited as a part of a multiple endocrine neoplasia (MEN) syndrome. They are produced by overexpression of PRAD-1 and RET gene or due to inactivation of the MEN 1 gene, retinoblastoma (RB) gene, and the gene on chromosome 1b.

PRAD-1

Parathyroid adenoma-1, or PRAD-1, is a gene on chromosome 11 that controls the cell cycle. Overexpression of PRAD-1, resulting in overexpression of the regulatory protein cyclin D1, is responsible for at least 50 percent of sporadic parathyroid adenomas.

MENIN

The MEN-1, or MENIN, gene is a tumour suppressor gene located on chromosome 11q13. Somatic mutations of this gene cause MEN-1, but are found in approximately 25 percent of sporadic parathyroid adenomas. MEN-1 is characterized by parathyroid, pancreatic islet cell and pituitary tumours, with 95 percent having hyperparathyroidism (HPT) due to parathyroid tumours. There are over 250 different mutations of the MENIN gene found in the kindred of MEN-1 patients, and 90–95 percent of MEN-1 patients have demonstrable mutations.

RET protooncogene

The cRET, or MEN-2, gene is a protooncogene located on chromosome 10. Mutations of this gene result in MEN-2, which has two subtypes. MEN-2A is the more common type, characterized by medullary carcinoma of the thyroid, pheochromocytoma and parathyroid tumours, but the latter are only present in 20 percent, reflecting the lower virulence of the multiglandular disease. MEN-2B is characterized by medullary carcinoma of the thyroid and pheochromocytoma, marfanoid features and mucosal neuromas, but without parathyroid tumours. The cRET genetic mutation is found in 90 percent of patients, so that mutational analysis of the cRET gene is useful in the screening and management of first-degree relatives.

RB gene

The RB gene is a tumour suppressor gene present on chromosome 13q14. Allelic deletion of the RB gene is found in parathyroid tumours, especially in parathyroid carcinoma, so that with the presence of abnormal RB protein staining may play an important role in differentiating benign and malignant parathyroid disease.

Gene on chromosome 1b

This is a protooncogene located on the chromosome 1q21–q31, and mutation of this gene is found in 40 percent of sporadic parathyroid adenomas. In the hereditary form there is an association with a family history of mandibular and maxillary tumours, Wilm's tumour and adult nephroblastoma, as well as an increased risk of parathyroid cancer.

Gene on chromosome Xp11

This is a tumour suppressor gene, which may play an important role in the refractory secondary HPT seen in

chronic renal failure. Hyperplasia of parathyroid glands in these patients is due to monoclonal mechanisms and produces nodular hyperplasia.

Gene for CaR

The calcium sensing receptor has a key role in the calcium-mediated regulation of PTH secretion, parathyroid cellular proliferation and probably the mRNA levels of pre-proPTH.³ Inactivating mutations of this gene produce two types of hypercalcaemic disorders that reset the 'set-point' of calcium-mediated PTH secretion. Heterozygous mutations result in familial hypocalciuric hypercalcaemia (FHH), with a mild, generally asymptomatic hypercalcaemia. Individuals with homozygous mutations have parathyroid glands with much more marked calcium resistance, presenting with neonatal severe hyperparathyroidism (NSHPT) and profound hypercalcaemia and HPT.

PTH-receptor gene

This gene is located on chromosome 3 and activated mutation of this gene results in Jansen's disease. It is an autosomal dominant disorder characterized by dwarfism, hypercalcaemia and hypophosphataemia, with normal or undetectable serum PTH. William's syndrome is an autosomal dominant disorder, with a genetic defect located on chromosome 7, characterized by infantile hypercalcaemia, supraaortic stenosis, psychomotor retardation and elfin facies.

PRIMARY HYPERPARATHYROIDISM

Hyperparathyroidism can be caused by primary parathyroid gland dysfunction or by a variety of secondary causes that lower calcium levels or raise phosphate levels. Hypoparathyroidism is usually a complication of thyroid surgery, from removal or damage to parathyroid glands. Its presentation and management are discussed in Chapter 28, The thyroid: nonmalignant disease.

Normally, PTH secretion is exceedingly sensitive to changes in serum calcium, with PTH changes occurring within seconds, sequentially and graded.³ The immediate effect of lowered calcium is the release of preformed PTH from secretory vesicles, followed by a decrease in the degradation of PTH in the parathyroid cell, so that more intact hormone is released. If the stimulus persists then there is an upregulation of the expression of pre-proPTH mRNA. If the stimulus lasts for an extensive period of time, then parathyroid chief cells begin to proliferate within days (as in chronic renal failure). In primary hyperparathyroidism (pHPT) this sensitive feedback mechanism is lost.

Diagnosis

Diagnosis of pHPT is made when there is a high serum calcium, with an abnormally high or nonsuppressed PTH level. Occasionally, it may be difficult to identify milder forms of pHPT, as PTH is not released at an even rate, so repeated measurements of serum PTH and calcium may be required to make a biochemical diagnosis.

pHPT occurs in two forms, as nonfamilial or sporadic in 95 percent, and as familial or hereditary in 5 percent. In the hereditary form, pHPT may be a part of one of the MEN syndromes.

Incidence

The exact incidence of pHPT is unknown, but is increasing with the use of multichannel autoanalysers picking up hypercalcaemia more often. Overall, the incidence in men is around 0.3 percent, and in women 1–3 percent, but in autopsy examination this sex discrepancy disappears, perhaps reflecting the more likely diagnosis in women being screened for osteoporosis. In women, the incidence rises with age and could be as high as 1 in 500, with a rate of 2.6 percent in women aged between 55 and 75 years.⁵

Pathology

The aetiology of primary HPT is unknown, but radiotherapy to the head and neck during childhood can predispose to either adenoma or hyperplasia.⁶ The pathology of pHPT is adenoma in 80 percent, hyperplasia in 15–20 percent and carcinoma in 1 percent of patients.

ADENOMA

Parathyroid adenomas are usually solitary, with the other glands showing evidence of suppressed activity. Double or multiple adenomas may occur occasionally, but more likely are misdiagnosed hyperplasia. Parathyroid tumour more often affects the lower glands than the upper glands, and intrathyroidic and intrathyroidal adenomas are not uncommon.

The adenomas are generally ovoid, soft, reddish-brown tumours, usually a little darker than the normal glands. Microscopically, they are characterized by varying compositions of chief, clear and oxyphil cells, with chief-cell adenoma by far the most common. Parathyroid adenomas generally exhibit a peripheral rim of condensed normal parathyroid tissue, separated by a slender capsule.

HYPERPLASIA

Parathyroid hyperplasia affects more than one gland, as a result of an increase in parathyroid parenchyma. The

enlarged glands are rounded or grossly lobulated, and grey-brown in colour, but the process may not involve all glands or involve them uniformly.

Microscopically, primary chief-cell or nodular hyperplasia is the predominant finding, but a multiplicity of cell types can be found. Nodular chief-cell hyperplasia is the characteristic pathology of the parathyroids in MEN-1 syndrome.

CARCINOMA

Parathyroid carcinomas are nearly always functioning tumours and account for approximately 1 percent of cases of pHPT, usually with a very high serum calcium and PTH. These tumours are often large and clinically palpable, usually greater than 2 cm in size, and appear firm, greyish-white and adherent to adjacent structures.

Microscopically, carcinoma shows features of malignancy, such as invasion of the capsule, vascular invasion, marked fibrosis with nodule formation, focal areas of necrosis, cellular atypia and a high mitotic rate. Chief and oxyphil cells are predominantly seen. Flow cytometry studies show that an aberrant ploidy pattern is associated with a bad prognosis. It is extremely difficult for the pathologist to make the diagnosis at frozen and paraffin section. Parathyroid carcinoma spreads by local invasion and lymphatic permeation, and distant metastasis occurs to lung, liver and bones. Treatment involves en bloc resection of parathyroid and adjacent structures, including ipsilateral thyroid lobectomy and node dissection. [**]

Clinical features

In asymptomatic, ambulatory patients, over 80 percent of patients with hypercalcaemia will have pHPT, but this falls to less than a third in symptomatic and/or hospitalized patients. More often in this hospital group, severe symptomatic hypercalcaemia is caused by malignant disease. The majority of patients with pHPT have no symptoms or only mild symptoms, and are picked up on biochemical screening for another reason. Symptomatic presentation due to hypercalcaemia with the classical rhyme of bones, stones, abdominal groans and psychic moans is extremely rare.

MUSCULOSKELETAL

The most common symptoms are muscular weakness, bone and joint pain; fatigue and lethargy are very common. Patients have reduced bone mineral density, but the severe form of bone disease known as osteitis fibrosa cystica is extremely rare in developed countries. Parathyroidectomy leads to incomplete improvement of bone density, but does improve muscle function and relieves the feeling of tiredness.

RENAL

The usual symptoms are renal and ureteric stones; renal failure and nephrocalcinosis are extremely rare. Parathyroidectomy lowers the frequency of recurrent stones.

GASTROINTESTINAL

Abdominal pain can arise from chronic constipation, but the linkage between peptic ulceration, pancreatitis and pHPT is controversial. Improvement of symptoms after parathyroidectomy is unpredictable.

PSYCHOLOGICAL

Prospective analyses have suggested that even apparently asymptomatic patients with pHPT may have psychiatric symptoms, which can be reversed by active treatment.⁷ Anxiety and depression, lassitude, dementia and loss of concentration or memory are the common symptoms. Parathyroidectomy reverses the dementia-like symptoms in the elderly population, and significant improvements can be made in other symptoms.⁸

METABOLIC 'SYNDROME'

pHPT is associated with a metabolic syndrome which carries an increased risk of premature death, even in mild hypercalcaemia, and increases with the extent of hypercalcaemia.

Diabetes mellitus and an impaired glucose tolerance can be seen due to peripheral insulin resistance. Blood lipid levels show a decrease in high-density lipoprotein (HDL) and low-density lipoprotein (LDL) levels and a rise in very low-density lipoprotein (VLDL) levels. Cardiovascular disorders, such as hypertension, left ventricular hypertrophy and valvular calcification, are known to be associated with pHPT. Many of these effects can be reversed or improved after parathyroidectomy. [****/**]

Investigations for HPT

pHPT is responsible for over 80 percent of cases of asymptomatic hypercalcaemia in the ambulatory population, but accounts for only 20 percent in the symptomatic or hospitalized population with hypercalcaemia.

BIOCHEMICAL

The common biochemical tests performed are plasma calcium, albumin, vitamin D and intact PTH. Measurements may have to be repeated due to the episodic secretion of PTH, which can result in normocalcaemic periods. A 24 hour urine collection for calcium will help to exclude FHH and lithium as causes of hypercalcaemia.

Complementary tests that may be helpful to support the diagnosis are plasma phosphate, creatinine and magnesium.

LOCALIZATION STUDIES

Preoperative localization of parathyroid tumours can locate abnormal glands in 80–85 percent of cases, which allows minimally invasive techniques to be used, with the potential for operation under local anaesthesia. Typically, localization is achieved by a combination of high-resolution ultrasound and ^{99m}Tc-sestamibi scan. Other investigations, such as selective angiography and venous sampling, CT and MRI will be needed if a second or subsequent operation is being planned.

Ultrasound

Ultrasound is cheap, noninvasive and can be used intraoperatively. Parathyroid adenoma is typically sonolucent (**Figure 31.1**) and colour Doppler will demonstrate the presence of an arterial signal at the vascular pole.⁹ Ultrasound can only be used to locate adenomas in the neck, with a sensitivity of around 85 percent in the unexplored neck, dropping to 40 percent in patients who have had a previous exploration.

Sestamibi scintiscan (MIBI = methoxyisobutylisonitrile)

Parathyroid adenoma concentrates ^{99m}Tc-labelled sestamibi because of the higher number of metabolically active mitochondria (**Figure 31.2**). It can be used to locate glands in either the neck or mediastinum with or without the addition of single photon emission computerized tomography (SPECT). Scanning can detect 87 percent of solitary adenomas, 55 percent of abnormal glands in patients with multiglandular disease and 75 percent of persistent or recurrent lesions in the previously explored neck.¹⁰ Diffuse hyperplasia will often lead to a negative scan as the parathyroid glands are less mitochondria-rich.

Figure 31.1 Ultrasound of a typical parathyroid adenoma.

Figure 31.2 Sestamibi scan showing right inferior parathyroid adenoma.

Selective venous sampling and angiography

In the patient who has had a previous failed exploration, perhaps due to a mediastinal adenoma, more invasive investigative measures may be needed in addition to sestamibi scan and ultrasound. **Selective angiography will**

Figure 31.3 Selective arteriogram showing a mediastinal parathyroid adenoma.

usually identify the missed gland, with a sensitivity of 90–95 percent, especially when combined with venous sampling for parathyroid hormone assay (**Figure 31.3**). Almost all enlarged glands are hypervascular, with a distinctive angiographic ‘blush’, resulting in a low false-positive rate.

Computed tomography and magnetic resonance imaging

Thin-slice computed tomography (CT) will visualize ectopic parathyroids in the anterior mediastinum, where ultrasound cannot see. CT and magnetic resonance imaging (MRI) have a sensitivity of 75–85 percent in an unexplored neck, which decreases to 45 percent for CT after previous surgery, but remains more accurate (50–75 percent) with MRI.

Positron emission tomography scanning

¹¹C-methionine positron emission tomography (PET) is clinically useful in highly preselected patients with recurrent pHPT, as well as in secondary and tertiary HPT, with a sensitivity of 83 percent, a specificity of 100 percent and an accuracy of 88 percent in successfully locating parathyroid adenomas.^{11, 12}

Indications for surgery

SYMPTOMATIC

All patients with symptomatic pHPT should have parathyroidectomy. The advantages of the operation

are:

- relief of muscle pain, lethargy and weakness;
- improvement in bone pain and the bone disease of hypercalcaemia;
- reduction in incidence of renal stones;
- improvement in psychiatric symptoms;
- reversal of many of the symptoms of 'metabolic syndrome'.

ASYMPTOMATIC

Opinions differ as to the correct management of patients without symptoms; however, the NIH Consensus Development Conference held in 1990 provided some guidelines.¹³ Patients with levels of calcium above 3.00 mmol/L should have parathyroidectomy with or without symptoms. Patients with mild HPT (calcium 2.85–3.00 mmol/L) should have surgery if any of the following criteria are fulfilled:

- creatinine clearance reduced by at least 30 percent;
- urine calcium excretion above 400 mg/24 hours;
- bone mass two standard deviations below that of age and sex-matched persons;
- age below 50 years;
- recent history of kidney stones;
- apparent neuromuscular or psychiatric symptoms;
- medical surveillance undesirable or unsuitable.

However, despite these guidelines, the authors feel that parathyroidectomy should be recommended for all patients with hypercalcaemia and pHPT, for the following reasons:

- the difficulty of determining symptoms preoperatively (especially psychiatric symptoms), that may be alleviated by surgery;
- approximately 50 percent of conservatively-treated asymptomatic patients become symptomatic;
- 6 percent develop renal stones, 5 percent develop bone disease and 5 percent develop psychological problems;¹⁴
- the present evidence shows untreated asymptomatic patients have increased mortality due to cardiovascular disease;¹⁵
- minimally invasive surgery under local anaesthesia is now possible;
- low rate of complications of parathyroidectomy in experienced hands;
- high rate of postoperative cure in experienced hands.

Management of pHPT

MEDICAL THERAPY OF HYPERCALCAEMIA

The treatment of pHPT is predominantly surgical. Prior to surgery, the medical treatment of hypercalcaemia will depend on its severity. The main aim is to reduce

hypercalcaemia as rapidly as possible and then to diagnose the underlying cause. Mild (<3.0 mmol/L) to moderate (3–3.5 mmol/L) hypercalcaemia can generally be managed on an outpatient basis, whereas severe (>3.5 mmol/L) hypercalcaemia requires more vigorous inpatient treatment.

Acute treatment of hypercalcaemia involves rehydration with i.v. normal saline, diuretics and the use of bisphosphonates intravenously, such as pamidronate. Longer-term treatment requires maintenance of adequate hydration, a low calcium diet, oral bisphosphonates and parathyroidectomy if pHPT is present.¹⁶ An alternative for the future may be the use of a calcimimetic drug to interact with the calcium receptor on the parathyroid cell, decreasing serum PTH and ionized calcium concentrations.¹⁷ [***/**]

SURGICAL STRATEGIES

Conventional parathyroidectomy

Bilateral neck exploration in the conventional operation allows access to all four glands and the ability to diagnose hyperplasia, double adenoma and microadenoma that might be missed by minimally invasive techniques.¹⁸ Frozen section biopsy is useful in confirming parathyroid tissue, but differentiating adenoma from hyperplasia is only 60 percent reliable at frozen section and is better achieved by the assessment of an experienced surgeon.¹⁹

While exploring the parathyroid glands, it is essential to understand the following principles.

- The normal parathyroid gland tends to be approximately 5 mm in size, and can be seen to move independently within its fascial layer.
- Parathyroids tend to be symmetrically placed on each side.
- Most parathyroid glands are situated in the normal anatomical position, medial to the carotid arteries;
- superior glands are located behind the plane of the recurrent laryngeal nerve usually above the inferior thyroid pedicle (**Figure 31.4**).
- Inferior glands are found in front of the plane of the recurrent nerve, usually below the inferior thyroid pedicle, but their position is more variable.

Missing superior gland

Eighty percent of upper glands lie in a 2 cm radius 1 cm above the intersection of the inferior thyroid pedicle and the recurrent nerve (**Figure 31.5**). If not found there, it may help to divide the superior part of the sternothyroid muscle and/or take down the superior pole of the thyroid to improve exposure. It may be that a large adenoma has descended into the tracheo-oesophageal groove, so a search behind the oesophagus, higher in the retropharyngeal space and down into the posterior mediastinum should be made.

Figure 31.4 Normal right upper parathyroid gland (at tip of metal forceps) in front of the plane of the recurrent laryngeal nerve (blue arrow).

Figure 31.5 Right upper parathyroid adenoma in tracheo-oesophageal groove (blue arrow).

Missing inferior gland

Most commonly, the inferior gland is found within a 1 cm radius of the lower pole of the thyroid, but its position is more variable than the upper gland. If the inferior gland is missing, a thymectomy should be performed which may reveal the adenoma lying within the gland (Figure 31.6). The surgeon should also consider an undescended inferior parathyroid, particularly if the ipsilateral thymus is absent from its normal position. The carotid sheath should be opened and explored from the hyoid to the thoracic inlet, and consideration also given to a possible intrathyroidal adenoma.

Figure 31.6 Parathyroid adenoma in thymus.

Indication for mediastinal exploration

If four normal glands have been found, the neck should be closed and a reassessment made of the original diagnosis. Further dissection at this point places the blood supply of the remaining parathyroids at risk, as well as increasing the potential for recurrent nerve damage. Post-operatively, the patient should be reinvestigated, including selective venous sampling.

Less than 1 percent of patients need a mediastinotomy as the majority of mediastinal lesions are actually in the thymus, which can be safely removed from the neck. The advantages of staging mediastinal surgery as a second procedure are:

- dissection in the neck may disrupt an adenoma's blood supply, turning an apparently negative exploration into a successful result;
- the pathologist may identify parathyroid tissue, for example in the thymus, which was missed at operation;
- there is an opportunity to reconfirm or change the diagnosis;
- angiographic ablation can be performed for inaccessible mediastinal glands.

Scan-directed minimally invasive open parathyroidectomy

The technique of scan-directed minimally invasive open parathyroidectomy (MIP) has rapidly gained favour with the advent of accurate preoperative localization techniques, which allow a targeted approach to the adenoma, minimizing dissection and potential complications.²⁰ The parathyroid adenoma is localized by sestamibi scan and ultrasound, and only the area identified is explored, either under general or local anaesthesia. Access is either through a small lateral transverse incision, or one made along the medial border of the sternocleidomastoid muscle. Ideally, the success of MIP should be confirmed by measurement of intraoperative PTH.²¹ If scans are concordant, then MIP should cure between 92 and 95 percent of patients. [***/**]

Radio-guided parathyroidectomy

Radio-guided parathyroidectomy, popularized by Norman and Chheda,²² relies on uptake into the adenoma of ^{99m}Tc-labelled sestamibi given two hours before

operation, then a hand-held gamma probe is used intraoperatively. Focused dissection is performed in the area of highest activity and the radioactive gland is removed. The main disadvantages are cost and the organizational difficulties of arranging and timing of the scan before operation. [**]

Video-assisted and endoscopic parathyroidectomy

Minimally invasive video-assisted (MIVAP) and endoscopic parathyroidectomy are more recent techniques that result in a smaller scar in the neck and a quicker recovery, but at the expense of longer operating times and higher costs. Endoscopic parathyroidectomy uses gas insufflation and several 3 mm ports in the neck. Miccoli *et al.*^{23, 24} modified this operation, substituting a gasless, video-assisted approach, in combination with intraoperative PTH measurement. Ikeda *et al.*²⁵ have gone even further to remove the scars from the neck by approaching the parathyroid tumour via an axillary or a submammary approach. [****/***]

Results of parathyroidectomy

CURE RATE

Many patients will require post-operative calcium and vitamin D supplementation until the suppressed glands recover their function. At the first operation, more than 95 percent of pHPT patients will be cured, with 83 percent of those requiring reoperation. The outcome is significantly dependent on how many parathyroidectomies are carried out by a given surgeon per year, with higher failure rates for those performing less than 15 cases per year.²⁶

COMPLICATIONS

The post-operative complication rate is under 1 percent after primary operations and less than 5 percent after reoperative surgery, with a mortality rate well below 1 percent. Approximately 8 percent of primary operations for pHPT result in recurrent or persistent disease, this is higher in multigland disease and particularly the MEN syndromes, where it may be as high as 40 percent.

PERSISTENT OR RECURRENT HPT

Persistent HPT is defined as the presence of hypercalcaemia in the immediate postoperative period or within six months. Recurrent HPT is defined as the return of hypercalcaemia after six months of post-operative normocalcaemia or hypocalcaemia, which is caused by inadequate resection of diseased glands, such as regrowth of residual, unresected, hyperplastic gland after subtotal parathyroidectomy, incomplete resection of an adenoma, rupture and spillage of parathyroid cells (parathymomatosis) or recurrence of parathyroid carcinoma.²⁷

Patients with persistent or recurrent HPT need to be reinvestigated more vigorously and the diagnosis reconfirmed prior to any second operation. Mild asymptomatic or normocalcaemic HPT may not need reoperation at all, but symptomatic patients with high serum calcium and renal or bony disease will need a second exploration.

Reoperations may be relatively uncomplicated, but generally are technically difficult, with a high complication rate and low success rate in inexperienced hands. Injury to the recurrent laryngeal nerve and permanent hypoparathyroidism occur in 8 percent of patients. The technique involves a 'back door' approach to a focused dissection of the abnormal area identified at reinvestigation. The sites of missed adenoma are in the normal positions in 40 percent, posterior superior mediastinum in 30 percent, intrathymic in 15 percent, posterior midline in 5 percent, mediastinal in 5 percent, intrathyroidal in 2 percent and other areas 3 percent. Mediastinal glands are usually found around the aortic arch, superior vena cava and aorto-pulmonary window.²⁸

SECONDARY AND TERTIARY HPT

Secondary HPT is caused by hypocalcaemia or phosphate retention, typically seen in chronic renal failure. Less common causes are vitamin D deficiency and lithium ingestion.

Chronic renal failure causes hyperphosphataemia and hypocalcaemia stimulating diffuse hyperplasia of all four glands and a rise in serum PTH. Prolonged stimulation of parathyroid glands results in nodular hyperplasia from monoclonal cell proliferation and a decrease in vitamin D receptor and CaR density. This results in resistance to medical treatment.²⁹

In tertiary HPT, one of the hyperplastic nodules becomes autonomous due to alteration in PTH-gene transcription, resulting in hypercalcaemia and raised PTH similar to pHPT.

Medical treatment

The primary treatment of secondary and tertiary HPT is predominantly medical, through management of chronic renal failure by medical manipulation of phosphate levels and peritoneal or haemodialysis. Renal transplantation usually cures secondary HPT.

Parathyroidectomy

Twenty-eight percent of renal patients on dialysis have secondary HPT, and 10 percent of patients who have had successful renal transplantation develop either secondary or tertiary HPT. These patients will generally need surgical parathyroidectomy.

There are a number of different surgical strategies available: total parathyroidectomy, with or without autotransplantation, and subtotal parathyroidectomy. Some endocrine surgeons prefer subtotal parathyroidectomy, removing three-and-a-half glands, but it is extremely difficult to judge the correct amount of parathyroid tissue to achieve normocalcaemia. In addition, graft-dependent recurrence occurs in up to 75 percent of patients on dialysis who have had autotransplantation, and 10 percent develop graft failure with hypocalcaemia.³⁰ For this reason, the authors favour total parathyroidectomy and transcervical thymectomy. [****/****/****]

KEY POINTS

- Primary hyperparathyroidism and malignancy are responsible for 90 percent of hypercalcaemia.
- Eighty percent of pHPT is due to single gland disease.
- Sestamibi and ultrasound localization allows unilateral exploration of the neck.
- Intraoperative quick PTH assay is an essential tool.
- Management of secondary HPT is difficult.
- Parathyroid carcinoma is rare; when suspected will require en bloc excision with ipsilateral thyroidectomy.

Best clinical practice

- ✓ The approach to pHPT is the same as for any endocrine condition, following five basic principles: confirmation of endocrine diagnosis; localization of the tumour or tumours; ensuring the patient is biochemically safe for surgery; deciding necessity for operation; choosing a suitable procedure.
- ✓ Minimal diagnostic investigations:
 - biochemical tests: calcium, PTH, vitamin D and 24 hour urine calcium;
 - localization studies: ultrasound, sestamibi scan;
 - before reoperation: CT or MRI, PET and selective venous sampling and angiography. [****/****/****]
- ✓ Indications for parathyroidectomy:
 - symptomatic hypercalcaemia;
 - asymptomatic hypercalcaemia with: calcium >3 mmol/L; calcium <3 mmol/L with renal disease, bone disease, young age (<50 years) or 'metabolic syndrome'. [Grade A/B]
- ✓ Plan of parathyroid exploration:
 - find recurrent laryngeal nerve;

- look for upper parathyroid (2 cm radius from 1 cm above intersection of RLN and ITA);
- missing upper: look tracheo-oesophageal groove, retro-oesophageal and retropharyngeal spaces;
- look for lower parathyroid (inferior thyroid pole to thymus);
- missing lower: perform thymectomy, look in carotid sheath;
- consider thyroid lobectomy;
- stop, then reassess diagnosis and consider mediastinal exploration. [****/****/****]

- ✓ Revision parathyroid surgery. Recurrent or persistent HPT requires:
 - reinvestigation to confirm diagnosis and localize tumour;
 - more invasive investigation, for example selective venous sampling;
 - assess need for surgery;
 - 'back door' approach between sternocleidomastoid and strap muscles;
 - focused exploration in identified area, with meticulous dissection. [****/****]

Deficiencies in current knowledge and areas for future research

The main problem in primary hyperparathyroidism is separating multiple gland disease from single gland disease. If accurately detected, single gland disease can be easily managed by minimally invasive techniques, either open, video-assisted or endoscopically, with the potential for operation under local anaesthetic. Thus, there is a great need for an accurate scan that will separate single from multiple gland disease.

Our wish list for the future would therefore be:

- more accurate forms of scanning;
- a preoperative method of separating carcinoma of the parathyroid from benign disease;
- effective, long-acting inhibitors of PTH secretion by either hyperplastic glands or adenomas, such as calcimimetic drugs;
- a more effective way of controlling preoperative hypercalcaemia without the inherent risk of post-operative hungry bone disease.

Head and neck manifestations of endocrine disease

JONATHAN M MORGAN AND THOMAS McCaffrey

Introduction	398	Pancreatic islet cell disease	401
Pituitary disease	399	Pregnancy and gonadal disease	402
Thyroid disease	399	Key points	403
Adrenal disease	401	References	403
Parathyroid disease	401		

SEARCH STRATEGY AND EVIDENCE-BASE

Information for this chapter was gathered by searching Medline using the key words head and neck, endocrine disease, as well as using the specific disease names. Due to the nature of the context of this chapter, studies cited here are predominantly retrospective and/or observational, unless specifically stated in the body of the text, and therefore fall into evidence levels 3 and 4.

INTRODUCTION

Although endocrine disorders usually produce symptoms and findings that are primarily systemic, specific and localized manifestations of endocrine disease may occur early or predominantly in the head and neck region. Awareness of these presentations may lead to the early diagnosis of the underlying endocrine disease. This chapter presents the symptoms and findings in the head and neck that are caused by changes in hormone levels or endocrine disease. We begin with perturbations of the hormones produced in the pituitary, then progress to the thyroid, adrenals, pancreas and gonads. We should also note that altered physiologic states, including pregnancy, and paraendocrine diseases are defined by changes in hormone levels. These changes in physiologic states are also seen in the head and neck region and are addressed in this chapter.

The regulation of the endocrine system is based upon a basic principle of negative and positive feedback loops. The complex interactions of the endocrine system are beyond the scope of this text and we would refer you to an endocrinology text for a more complete description.

The feedback mechanism begins with neuroendocrine regulation. The hypothalamus produces chemical mediators (growth hormone-releasing hormone (GHRH), leuteinizing hormone-releasing hormone (LHRH), thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH) and dopamine (prolactin inhibiting hormone.)) These mediators travel via a portal system to the anterior pituitary and in turn regulate the release of growth hormone (GH), leuteinizing hormone (LH) and follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), adrenocorticotrophic hormone (ACTH) and prolactin. The hypothalamus also produces vasopressin and oxytocin and these are stored in the posterior pituitary. The main feedback loop continues from the hormones of the anterior pituitary to the three target endocrine glands, the gonads, adrenal cortex and the thyroid, these in turn produce an additional set of hormones that effect multiple glands and organ systems. There are many possible mechanisms that can cause a disturbance in this feedback loop. The result of these disturbances being a real or apparent increase or decrease of hormone levels, which in turn cause the signs and symptoms of endocrine disease. Hypothalamic disease

can cause hypopituitarism and all of the associated symptoms, although typically head and neck manifestations are rare in diseases of the hypothalamus.

PITUITARY DISEASE

Diseases of the anterior pituitary can result in the production of many different hormones, although otolaryngologic manifestations are rare. The exception is acromegaly, or the overproduction of GH (somatotropin). The overproduction of GH prior to epiphyseal closure results in gigantism. Acromegaly is an insidious chronic debilitating disease. This is a rare disease with a prevalence of 50–70 cases per million and an incidence of 3–4 per million per year.

The disease presents most frequently in middle age and has no predilection for men or women. Facial features are well documented. **Table 32.1** documents all of the head and neck manifestations. The pathophysiology of increased GH is the result of pituitary adenomas (in almost all cases). Typically, the tumour is found laterally in the sella, where somatotrophs are abundant. However, rare cases have been reported of tumours along the migration line of Rathke's pouch, including the sphenoid sinus and the parapharyngeal space.⁷

Regional symptoms secondary to either mass effect of direct extension of pituitary adenomas most commonly present with blurred vision and visual field defects. (**Figure 32.1**). However, several pathways of extension of invasive adenomas have been defined:⁸

- pharyngeal extension via the floor of the sella and sphenoid sinus;
- hypothalamic extension via the floor of the third ventricle;
- temporal extension;
- invasion of the cavernous sinus and associated cranial nerves;
- posterior subtentorial extension involving the third, fourth and fifth nerves;
- frontal extension.

Extension of the tumour into the middle ear and external auditory canal is a very rare presentation.⁹ Another rare

presentation of invasive pituitary adenomas is nasal obstruction.¹⁰ These tumours are typically diagnosed by transnasal biopsy of the mass.

THYROID DISEASE

The thyroid is also under the control of the hypothalamic-pituitary axis. Hypothyroidism is caused by many processes including the following: thyroid agenesis, surgical removal (thyroidectomy and laryngectomy), therapeutic irradiation (I^{131} or external radiation), autoimmune (Hashimoto's) thyroiditis, replacement by cancer or other disease, post-thyroiditis (acute or subacute), inhibition of thyroid hormone synthesis, iodine deficiency, excess iodine in susceptible patients, antithyroid drugs, inherited enzyme defects and post-partum. The incidence of hypothyroidism increases with age, and affects women four- to six-times as frequently as men. It occurs at all ages but gradually rises with age and peaks at 40–60 years. Up to 5 percent of persons older than age 65 have clinically overt hypothyroidism, whereas 15 percent have subclinical hypothyroidism marked only by serum TSH elevations. General symptoms include weakness, dry and coarse skin, myxedema and pallor. The hair of these

Table 32.1 Signs and symptoms of acromegaly manifested in the head and neck.

General	Oral	Nasal	Laryngeal
Headaches	Enlarged tongue	Sinus congestion	Hoarseness
Visual field changes	Malocclusion	Rhinorrhoea	Decreases vocal pitch
Prognathism ¹	Mandibular protrusion	Enlarged paranasal sinuses ³	Asymmetric enlargement of epiglottis, aryepiglottic folds, false and true vocal cords
Obstructive sleep apnoea ²			Cricothyroid arthritis ⁴
Coarse facial features			Vocal cord paresis/paralysis ⁵
Oily skin			Airway obstruction ⁶
Soft tissue and bony enlargement			

patients may be dry and fine, and they may suffer from alopecia. A classic symptom of hypothyroidism is the loss of the outer third of the eyebrows, also known as Queen Anne's eyebrows.

Vocal manifestations include hoarseness and a generalized slow speech rate. These patients may exhibit a low pitch and decreased vocal clarity. It was first postulated that this was due to central oedema of the vagal nuclei. Ritter noted that there was retention of proteinaceous fluid, high in mucopolysaccharides within the mucosa of the larynx in rats rendered hypothyroid by treatment with either propothiouracil, or radioactive I^{131} .¹¹

Rhinitis is a common complaint of patients with hypothyroidism. There is a correlation between hypothyroidism and rhinitis, however, no clear definition of the pathophysiology has been elucidated. Proetz^{12,13} assessed 130 hypothyroid patients and found nasal congestion, rhinorrhea, pale wet nasal mucosa, as well as rarely a dry red ('chapped') mucosa. Mucosal biopsy revealed non-specific inflammatory changes only. In a study of 66 hypothyroid patients, Gupta¹⁴ described symptoms of nasal stuffiness in 64 percent and increased colds and rhinorrhea in 55 percent. Rhinoscopy revealed pale, boggy mucosa in 41 percent and erythematous dry mucosa in 27 percent. Biopsies of 16 patients showed increased sub-mucosal acid mucopolysaccharide ground substance and glandular hypertrophy. In general, symptoms of nonallergic rhinitis are common for patients with hypothyroidism. However, undiagnosed hypothyroidism among patients with uncomplicated rhinitis is very low.^{15,16} Therefore, tests of thyroid function of patients with nonallergic rhinitis should be reserved for patients with other systemic symptoms of hypothyroidism.¹⁷ [Grade D]

Vestibular and otologic symptoms of hypothyroidism include vertigo, hearing loss and pruritic external auditory canals; the latter has been postulated to be due to the decrease of cerumen production. As many as two-thirds of patients with hypothyroidism suffer from vertigo. The attacks are typically mild and brief and are not associated with changes in ENG or hearing loss.¹⁸ These patients can also experience hearing loss. Although this is much more common in congenital disease, approximately 30–40 percent of patients with myxoedema suffer from bilateral sensorineural hearing loss. These patients can also experience conductive losses secondary to Eustachian tube mucosal oedema.¹⁹

Congenital hypothyroidism (cretinism) is a rare disease with a higher incidence in the underdeveloped nations. Head and neck manifestations of affected children are puffy face, yellowish skin, flat nose and enlarged tongue that can protrude from an open mouth. Fontanels and sutures may be widened, and the child's cry is hoarse. A goitre is characteristic of endemic cretinism, but the sporadic type caused by thyroid agenesis or dysgenesis typically has no palpable thyroid. Sensorineural hearing loss is progressive and responds to early treatment with thyroid hormone replacement. Bilateral sensorineural

hearing loss is more common in endemic cretinism, whereas sporadic cretinism tends to exhibit either a conductive, mixed or sensorineural hearing loss.²⁰

Pendred's syndrome is an autosomal recessive disorder that is characterized by a goitre and progressive sensorineural hearing loss. The children are typically euthyroid and have an abnormal perchlorate discharge. The hearing loss is more pronounced in higher frequencies and recruitment is present, indicating a lesion of the cochlea. This syndrome results from an inborn defect in thyroid hormone synthesis, a peroxidase defect in iodine metabolism.

Graves' disease and toxic nodular goitre account for more than 90 percent of hyperthyroidism and thyrotoxicosis, both more common in women. Graves' disease is classically manifested by an infiltrative ophthalmopathy (**Figure 32.2**). This is a lymphocytic inflammatory reaction that infiltrates the extraocular muscles and orbital fat; the fibroblasts proliferate and deposit glycosaminoglycans, predominately hyaluronic acid.²¹ As enlargement of orbital muscle and fat progresses, the bony walls of the orbit will not allow any increase in volume, therefore proptosis occurs. With an average orbital volume of 26 mL in healthy adults, an increase of only 4 mL in the volume of the orbital contents will result in 6 mm of proptosis. As the proptosis progresses, the protective mechanisms of the cornea are diminished. This can cause exposure, desiccation, irritation and, ultimately, ulceration and blindness if not treated. The inflammatory reaction in turn evokes a deposition of collagen into the extraocular muscles and this results in a restrictive ophthalmoplegia. Optic nerve involvement as a result of compression at the orbital apex by the enlarged extraocular muscles²² is another later finding in Graves' disease.

Lid lag and the appearance of a 'stare' are ocular manifestations of thyrotoxicosis and are often seen in the earliest forms of Graves' disease. This is the result of an increased sympathetic sensitivity to catecholamines.²³ Generalized tremors are common in patients with thyrotoxicosis. In the head and neck these manifest as fine tremors of the lips and the tongue (more evident when it is protruding²⁴). Vocal changes are often noted in these patients as well. Although no true dysphonia is noted, there is a tremulous voice that is a result of the increased respiratory rate and the resultant decreased vital

Figure 32.2 A patient with Graves' ophthalmopathy showing proptosis and lid retraction characteristic of this condition.

capacity.²⁵ Less common manifestations are osteoporosis of the mandible and maxilla and dark pigment deposits in the buccal mucosa.

Goitre, or neck masses, are very common in patients with thyrotoxicosis, as well as thyroid neoplasia. Neoplasia will be addressed in another chapter in this text, however, it should be noted that dysphagia, hoarseness, haemoptysis and haematemesis are all common symptoms and should alert the otolaryngologist to possible thyroid neoplasia.

ADRENAL DISEASE

Of the diseases of the adrenal gland, or disease processes that cause perturbations in the hormones produced within the adrenal gland, Cushing's syndrome/disease is the one with the most significant head and neck manifestations. Common causes of Cushing's syndrome/disease include adrenal hyperplasia, adrenal adenoma/carcinoma, ectopic production of ACTH and iatrogenic causes. A rare cause of ectopic production of ACTH is medullary thyroid carcinoma (MTC). These tumours have demonstrable adrenocorticotropin immunoreactivity and can release adrenocorticotropin. Classic signs of this disease are central obesity and 'moon' faces. Androgen excess causes acne and hirsutism. Patients with Cushing's disease are at an increased risk of infectious diseases, oral candidiasis is a common problem. Generalized muscle weakness (steroid myopathy) can cause difficulties with phonation and deglutition. In contrast to Cushing's disease, adrenocortical insufficiency (Addison's disease) has oral mucosal hyperpigmentation and generalized muscle weakness that results in vocal weakness.

PARATHYROID DISEASE

Patients with hypoparathyroidism display many common head and neck signs and symptoms. The patients who suffer from hypoparathyroidism and resulting hypocalcaemia complain of perioral tingling and numbness. Hoarseness, aphonia and stridor are the typical vocal manifestations of laryngospasm seen with tetani. Chvostek's sign is also commonly seen with tetani (however, as many as 10 percent of normal patients will have a positive sign). Chvostek's sign is elicited by percussing over the facial nerve, anterior to the tragus. Facial muscle twitching is a positive response. Long-term hypocalcaemia can cause enamel defects and hypoplasia of the teeth.

Hyperparathyroidism and resulting hypercalcaemia is most often caused by parathyroid adenoma (in the ambulatory population), or malignancy (in the hospitalized population), although the differential for hypercalcaemia is long and getting longer. Classically, this disease process manifests as 'stones' (renalithiasis), 'bones' (bone

pain, with demineralization often seen in the skull), 'groans' (GI distress) and 'psychiatric overtones' (emotional changes including abnormal mentation). Osteitis fibrosis cystica or 'brown tumours' consisting of osteoblasts, osteoclasts and fibrous tissue are occasionally seen in the mandible and maxilla. In a small study, Simpson noted that auditory dysfunction, in three cases, and aphonia, in two cases, were reversed after removal of parathyroid adenomas.²⁶ He postulated that the high calcium ion concentration inhibited neural synaptic transmission, causing both of these symptoms.

Hyperparathyroidism also has a genetic component: multiple endocrine neoplasia (MEN) syndromes. MEN 1 (Wermer's syndrome) includes pituitary adenoma/hyperplasia, parathyroid adenoma/hyperplasia and pancreatic islet cell hyperplasia/adenoma/carcinoma. MEN 2A (Sipple syndrome) includes MTC, pheochromocytoma and parathyroid hyperplasia/adenoma. The MEN syndromes are inherited as autosomal dominant traits, therefore a family history is important to ascertain and decide if further work-up is necessary. Hyperparathyroidism is often the first manifestation of MEN 1 and usually appears after the patient reaches 18 years of age.

PANCREATIC ISLET CELL DISEASE

Diabetes mellitus (DM) is a disease that is caused by inadequate action of insulin, due to either resistance of end organs due to obesity reducing the insulin receptors on insulin responsive cells (type 2), or reduced levels of insulin due to autoimmune response to beta cells of the pancreas triggered by infection (type 1). Type 1 typically presents in patients under age 25 in 0.2–0.5 percent of the population, with no predilection for men or women. There is only a 50 percent concordance in identical twins. Prevalence of type 2 is 2–4 percent, and usually occurs in patients older than 40. There is a slight predilection for women. There is also a 100 percent concordance rate in identical twins. Head and neck manifestations of type 1 and type 2 diabetes are identical, and we will discuss these as a unit. Chronic manifestations of DM are secondary to micro and macrovascular disease, neuropathies (including peripheral, autonomic radiculopathy and mononeuropathy) as well as immunodeficiency secondary to impaired leukocyte/phagocyte function.²⁷ [***]

General considerations for otolaryngologists as surgeons revolve around the immunodeficiency and the decreased ability of diabetics to heal their surgical wounds and their increased susceptibility to infection. This should be considered prior to operating and glycaemic control should be optimized during the perioperative period. [Grade B]

The ocular findings of DM include diabetic retinopathy where venous dilatation leads to full-blown exudates and haemorrhage in the retina and vitreous

body. Haemorrhages in the conjunctiva and iris result in glycogen deposits, as well as depigmentation and neovascularization. Abnormal lens function leads to cataract formation. Mononeuropathy in the head and neck can be a presenting sign of DM. Bell's palsy has a high comorbidity with DM. In a retrospective study, 45 percent of patients between the ages of 10 and 19 who presented with Bell's palsy had DM, and in a series of 130 patients with DM, 66 percent presented with Bell's palsy.²⁸ Other neuropathies of the cranial nerves can result in unilateral vocal cord paralysis, dysphagia and dysphonia. Laryngeal nerve sections of moderate to severe diabetics showed segmental demyelination, axonal degeneration and concentric proliferation of Schwann cells.²⁹

Neuropathies affecting all other cranial nerves (with the exception of the olfactory and hypoglossal) have been documented in DM. Retrospective studies also show that as many as 50 percent of patients with diabetes have some manifestations of auditory dysfunction, and analysis of diabetic temporal bones has been found to contain PAS-positive lesions of the capillaries in the stria vascularis.³⁰ This is the same lesion seen in Kimmelstiel–Wilson disease (diabetic nephropathy). Animal studies of auditory brainstem responses (ABRs) have also shown significant prolongation of wave I as well as an elevation in the ABR threshold in diabetic rats.³¹

Equilibrium disorders are also very common for diabetics. Aetiologies for disequilibrium include peripheral neuropathy, direct toxicity of the vestibular end organ and fluctuations in glucose concentrations in the cerebral circulation. Diabetics routinely have abnormal electronystagmography and dynamic posturography. In a recent animal study, diabetic rats were shown to have prolonged latency and decreased amplitude of the first wave of the vestibular evoked potentials (VEPs). These parameters of the first wave have been shown to correlate with vestibular end-organ function.⁴

Diabetics are particularly prone to certain infections. Malignant otitis externa, commonly due to *Pseudomonas aeruginosa*, typically presents in the older diabetic with severe otalgia, otorrhoea, fever and leukocytosis. Granulation tissue at the bony-cartilagenous junction is a classic sign, and cranial nerve findings including facial nerve paralysis, as well as involvement of V, X, XI, XII are all poor prognostic indicators. Disease may spread beyond the external auditory canal and cause osteitis, chondritis and osteomyelitis of the temporal bone. Intracranial extension and death are possible if treatment is not thorough. Early cases are responsive to oral fluoroquinolones and meticulous and frequent debridements under the binocular microscope, more advanced cases require hospitalization and i.v. anti-*Pseudomonas* antibiotics and possible surgical debridement. [Grade B/C]

Another infection particular to diabetics and other immunocompromised hosts is invasive fungal sinusitis (rhinocerebral mucormycosis) (Figure 32.3). Presentation

© Hodder Arnold / Scott-Brown 7E

Figure 32.3 A diabetic patient with invasive fungal sinusitis involving the paranasal sinuses and orbit.

in the immunocompromised patient includes fever and localization of symptoms to the paranasal sinus area, such as orbital swelling, facial pain or nasal congestion. Physical examination may show necrosis of the nasal mucosa, indicative of mucormycosis and, in rare situations, actual hyphae. However, typical examination findings are indistinguishable from nonfungal causes of sinusitis. Anaesthesia of the nasal mucosa or cheeks, independent of topical anaesthetics, is suspicious for mucormycosis. The oral cavity always should be examined for invasion through the hard palate from the sinuses. Changes seen on sinus CT or plain radiographs are usually nonspecific and usually indistinguishable from bacterial sinusitis, although they may show bony erosion or soft-tissue invasion. Biopsy and culture are critical to making the diagnosis. Appropriate antifungal therapy and aggressive surgical debridement should be initiated as soon as possible.

PREGNANCY AND GONADAL DISEASE

The most common head and neck complaints during pregnancy are nasal obstruction and rhinorrhoea, typically serious and frequently accompanied by postnasal drip. Physical examination reveals hyperaemic mucosa with marked oedema and hypersecretory states. This is most common during the second and third trimesters and tends to continue for the duration of the pregnancy. Typically, resolution occurs within one week of parturition. Approximately 15–30 percent of pregnant females suffer from these symptoms.³² Although some patients have pre-existing allergic rhinitis, vasomotor rhinitis or sinus disease, and pregnancy merely exacerbates these conditions, many patients who do not have these underlying problems also suffer from this. The exact pathophysiology is not understood. It is clear that there are direct influences

of oestrogens on the nasal mucosa and resulting airflow, however no correlation has been shown between estradiol levels and nasal symptomatology.³³ [***]

Animals given oestrogen over a period of weeks to months show histologic changes of the mucosa, including proliferation of squamous metaplasia with increases in the cornification of the epithelium and a decrease in the number of cilia and goblet cells. Diffuse glandular hyperplasia with increased secretory activity of the acini was also seen. Vascular changes included endothelial proliferation and capillary and arteriolar swelling.³⁴ [***]

Symptomatic patients versus asymptomatic pregnant patients showed increased activity of succinic dehydrogenase indicative of increased secretory activity, and an increase in alkaline phosphatase concentration indicative of increased vascularity and a transfer of metabolites across plasma membranes.³⁵ The reasons why some women are symptomatic and others are not is not clearly understood.

Another common problem during pregnancy is an inflammatory gingival hyperplasia caused by increased gingival reactivity to local irritants. Typically seen in the patient's first trimester and commonly maintained until termination of the pregnancy, it may evolve into a 'pregnancy tumour' of the gingival. Biopsies of these have shown to be pyogenic granuloma. Menopause may be associated with several oral manifestations; the most common are desquamative gingivitis and generalized atrophic alterations of the oral mucosa.

Kallmen's syndrome and Turner's syndrome are two syndromes pertaining to the reproductive organs that deserve mention here. Kallmen's syndrome (hypogonadotropic hypogonadism) has two inheritance patterns: the first is X-linked recessive and the second is autosomal dominant with variable expressivity. The syndrome consists of gonadotropin deficiency secondary to LHRH deficiency in association with anosmia. This is often diagnosed when males fail to achieve puberty. There are variable degrees of dysosmia and even female carriers are shown to have decreased olfactory ability. Studies have shown that some of these patients have no olfactory bulb and stalks, while others have varying degrees of malformation of the olfactory epithelium (ranging from complete intact epithelium to complete agenesis). Other head and neck manifestations sometimes seen are midline facial deformities including cleft palate and deafness.

Turner's syndrome (gonadal dysgenesis) is characterized by an XO karyotype and occurs in 1 in 2500–10,000 live female births. This disease presents in females with gonadal dysgenesis, short stature and often a webbed neck and/or shield chest. Sensorineural, conductive or mixed hearing loss, which may be progressive, is often an early sign of Turner's syndrome in prepubertal females. These patients can also have a high arching palate, epicanthal folds and low-set ears.

KEY POINTS

- General awareness of endocrine disorders can aid in their early diagnosis as head and neck manifestations are often the presenting signs or symptoms.
- Patients with DM often complain of many common head and neck symptoms; this includes cranial neuropathies, sensorineural hearing loss and vestibular dysfunction.
- Patients with DM are susceptible to unique and invasive infections including malignant otitis externa and invasive fungal sinusitis.
- Pregnancy should be considered as a cause of rhinorrhea in the child-bearing age woman.
- Thyroid perturbations are often associated with abnormal function of the larynx, causing changes in pitch and clarity of speech, the nose, causing rhinitis, and the inner ear, causing vertigo and hearing loss.

SEARCH STRATEGY

The information in this chapter is supported by a PubMed search using the key words drug regulation and development, drug bioavailability, clinical pharmacokinetics and pharmacodynamics, drug compliance and monitoring, and adverse drug reactions.

INTRODUCTION

In clinical ear, nose and throat (ENT) practice, therapeutic decision making has become increasingly complex, particularly in the realm of drug prescribing. The increasing range of possible interventions and the changing expectations of patients have been accompanied by a dramatic rise in the number of drugs available. In 1932, the British Pharmacopoeia listed 213 medical products. By 2001, this figure had increased to 2760.

For clinicians, these factors have created a personal responsibility: we are now required to assess the relevant published evidence, to make a balanced therapeutic decision and to evaluate the outcome of that decision. Ideally, each drug prescription for a patient should be an individualized therapeutic plan which maximizes the clinical benefit and the patient's well-being while achieving the lowest toxicity and the lowest cost. To implement such a logical approach to drug therapy, a number of steps are known to be important. The clinician must:

- make an accurate diagnosis;
- understand the pathophysiology of the disease;

- have a good knowledge of the therapeutic options;
- select treatment: either no drug or an optimum drug and dosing schedule;
- monitor the effect of treatment and decide a therapeutic end point;
- maintain a 'therapeutic alliance' with the patient.

In this chapter, the aim is to discuss the regulatory mechanisms involved in drug control and to examine the factors which influence the therapeutic options for individual patients. In essence, the chapter sets out the principles involved in rational prescribing.

DRUG DEVELOPMENT

The discovery and development of a drug can take 15 years or more and involves many steps. Once a chemical with a potential therapeutic effect has been identified, a series of investigations in animals and humans is carried out to check whether the chemical is effective and whether it is safe to use. The first step in the development of a drug is to establish its pharmacokinetic and toxic

profile in animals. Three stages of trials in humans establish its potential for the treatment of disease. Phase I studies are primarily concerned with assessing a drug's safety, and are typically carried out on a small number of healthy volunteers, investigating the side effects as the dose increases. Phase II studies test for efficacy and may involve up to several hundred patients in a randomized, controlled trial. Finally, in phase III, most drugs are ideally entered into a randomized, double-blind, controlled trial involving several hundred to several thousand people, giving a more thorough understanding of the effectiveness, benefits and range of possible adverse reactions compared to an existing drug or placebo.

In the UK, once a drug has been successfully trialled, the pharmaceutical company applies to the Committee on Safety of Medicines (CSM) for a licence to launch the drug into the market. When a licence is received, the drug then joins the range of therapeutic options available to the clinician.

Drug regulatory systems

In most countries, a drug cannot be made legally available until a government-sponsored regulatory body has reviewed its safety and efficacy. This system was put in place in the UK in 1968 as a consequence of the thalidomide tragedy. Prior to this, there was no body in the UK which could prevent the marketing of a new medicinal product. Thalidomide was launched in Britain in 1958 as a sedative/hypnotic and for use in morning sickness. By 1961, however, it became clear that its use in early pregnancy was causally related to a congenital abnormality where the long bones in babies failed to develop. Around 1000 deformed babies were born in Britain as a result and around 10,000 worldwide. Following this tragedy, the Committee on Safety of Drugs was established, later to become the CSM following the Medicines Act of 1968. The CSM is an independent group of 34 clinicians, pharmacologists, toxicologists and pharmacists plus two lay appointees who advise the licensing authority (the health and agriculture ministers) on medicinal products. Adverse drug reactions are reported to the CSM by individual doctors, using a voluntary yellow card system. Although the voluntary system has yielded some impressive regulatory decisions, there is evidence that adverse reactions are significantly under-reported.^{1,2,3}

In 1995, the European Union (EU) established the European Agency for the Evaluation of Medicinal Products (EMA). This body coordinates the scientific evaluation of the safety, quality and efficacy of medicinal products for use throughout the EU. EMA employs a system of 'mutual recognition' of drug authorizations already granted by individual member states. In addition, EMA provides a centralized European evaluation for

new drugs and all decisions agreed under this new system are binding on member states.

Herbal medicines are largely outside the current regulatory systems. Used by 80 percent of the world's population and an increasing number of patients and practitioners in Europe and North America, herbal medicines include homeopathic, traditional herbal, Ayurvedic, naturopathic and native medicines. Most products are still unregulated, but in the UK, adverse reactions to Chinese and herbal medicine are reported to the CSM. The most comprehensive current regulatory system and information resource is provided by the German 'Commission E' monographs.

DRUG ADMINISTRATION

Following diagnosis of the disease and a decision to choose drug therapy, the clinician has to select an appropriate drug and decide the mode of administration. There is a wealth of information available about licensed drugs, including recommendations on delivery methods, dosage and dosage frequency, as well as information on known adverse effects. In considering the mode of administration, it is important for the clinician to assimilate and understand this information in order to select the best options for the individual patient.

Delivery methods

When a drug is used therapeutically the aim is to achieve an adequate concentration at the site of action and to maintain that concentration for as long as the effect is required. 'Systemic bioavailability' is a term used to describe the proportion of administered drug that reaches the systemic circulation and is available for distribution to the receptor site. The method of administration is a major determinant of bioavailability.

When a drug is given intravenously, the total dose enters the systemic circulation. This method achieves 100 percent bioavailability. However, use is limited by the constraints of venous access and issues of safety.

When a drug is given orally, the bioavailability depends on the extent of absorption from the gut and the metabolic activity of the liver as the drug circulates following absorption, known as the 'first pass effect'. This effect can substantially reduce the bioavailability of a drug. Most drugs are given orally and are therefore subject to 'first pass'.

Transnasal, sublingual, buccal and rectal formulations all avoid the first pass effect. The bioavailability depends only on the absorption across the mucosa. This mechanism may become an important consideration in some circumstances. For example, prochlorperazine in the buccal form may help a patient suffering an acute

labyrinthine attack in the presence of nausea and vomiting.

Transdermal formulations in the form of patches are absorbed through the skin and enter the systemic circulation directly. Absorption depends on lipid solubility and a concentration gradient being established across the dermis. Only some drugs are successful, one example being transdermal hyoscine for the treatment of motion sickness.

Intramuscular and subcutaneous preparations are limited in number because the absorption of drugs given by these routes is variable and often unpredictable, hindering their usefulness. Special consideration has to be given to the formulation of the drug and to the site of application. Drugs given intramuscularly are given into the deltoid muscle rather than gluteal, as absorption in the former is much more rapid due to the higher vascularity. A reduction in the rate of local absorption can be achieved, for example, by the use of adrenaline in combination with local anaesthetics administered subcutaneously, causing local vasoconstriction. Important subcutaneous preparations include heparin and insulin.

DRUG PHARMACOLOGY

The biological activity of a drug, whether therapeutic or toxic, is proportional to the concentration of the drug at the receptor site and the persistence of the drug's effect is directly related to the length of time the drug remains at the receptor site. Therefore, the biological activity of a drug is dependent on the rate and completeness of its absorption, distribution, metabolism and elimination. Within ENT practice, getting a drug to a receptor site can either be by direct application to that site (as with nasal antihistamines), or by administration via a site remote from the target (as with oral antihistamines in the case of allergic rhinitis). Whatever the method used, the drug must then diffuse across several membranes (absorption), distribute into a variety of tissues and fluids (distribution), be subject to a wide array of metabolizing enzymes

(metabolism) and finally be eliminated from the body (elimination).

Pharmacokinetics is the study of the rate of drug movement into and through body tissues. This information will help predict the time course and magnitude of the drug effect. The pharmacokinetics of a drug can be studied by regular analysis of plasma and urine samples following its administration, giving quantitative assessment of the rate of drug movement, metabolism and elimination. Plasma concentration is not necessarily the same as tissue concentration, but accurately reflects it in most therapeutic regimens and for practical clinical purposes is taken to be the same.

The study of the underlying mechanism of action of the drug at the receptor site and the resultant biological response is known as pharmacodynamics. Variations in this biological response due to genetically determined factors is known as pharmacogenetics.

Pharmacokinetics and clinical practice

Pharmacokinetics is the key factor in deciding on drug formulation and dosing frequency. To understand why, it is necessary to look at how drug concentration in the plasma (and by implication, at the receptor site) changes with time. After a drug is administered to the body in any form, the concentration of the drug in the plasma rises in keeping with absorption, then falls as a result of distribution, metabolism and elimination. **Figure 33.1** shows a typical profile of drug concentration in nasal tissue following instillation of nasal drops. The curve contains three features of interest.

C_{\max} This is the maximum level of drug in the plasma after a single administration (reflecting the maximum level of drug in the tissue). C_{\max} dictates the initial therapeutic and toxic responses. Most drug applications aim to have C_{\max} falling within the therapeutic range. The position of C_{\max} along the time-axis reflects the rate at which the drug becomes bioavailable.

Figure 33.1 Change in drug concentrations in the plasma/tissue following nasal administration.

T_{\max} This is the time taken to reach the maximum level of drug in the tissue.

Area under the curve The area under the curve (AUC) is a measure of the total amount of drug absorbed from a single dose. The bioavailability of the drug – that is, amount instilled versus amount absorbed – can be computed from the AUC.

Choosing the drug formulation

Figure 33.2 shows two curves representing the theoretical plasma/tissue concentration over time, following oral administration of equal doses of the same drug using different formulations. The total bioavailability, as indicated by the AUC, is the same in each case. However, the rate at which the drug becomes available depends on the formulation. For drugs such as analgesics, where a rapid plasma concentration is required after single dosing, choice of formulation may therefore be very important. For example, a soluble Diclofenac formulation giving a curve A would be preferable in the treatment of acute pain (such as postoperative tonsillectomy) rather than an enteric-coated formulation giving rise to a curve B. However, the latter would be more useful in the long-term treatment of chronic pain or for an antiinflammatory effect, allowing a reduction in the frequency of administration.

Deciding on dosing frequency

The frequency with which drugs are administered is governed by the rate at which they are metabolized and by the rate of clearance of the unmetabolized drug by the body. The overall rate of loss of the drug is described as the half-life ($t_{1/2}$): the time for the plasma concentration to fall to one half of the maximum value. The half-life in turn dictates the timing interval for delivering the second and subsequent doses; the recommended interval equals

Figure 33.2 Drug bioavailability curves for differing formulations.

the half-life of the drug. The resultant plasma level shows a series of peaks and troughs as in **Figure 33.3**. The peak and trough levels rise over time because each subsequent dose given at $t_{1/2}$ is additional to the quantity of the drug left behind from the earlier administration. Eventually, the size of the fall in plasma concentration after the peak equals the preceding rise and a steady state is reached. At steady state, the amount of drug eliminated from the body in a single dose interval is the same as the amount which enters it. Strictly speaking it is not a true steady state because the plasma concentration fluctuates. However, for practical purposes, a steady state is reached within a finite number of doses, usually between four and six. The concentration of drug in the plasma after multiple doses will be greater than the single dose, C_{\max} , but at all times should be within the therapeutic range.

If the half-life is long and it takes several days to reach a steady state, then an initial loading dose can be prescribed to overcome the delay in establishing the therapeutic effect. In **Figure 33.4**, a standard oral regime (Oral regime A) should ideally maintain a therapeutic plasma range throughout the drug administration. It can be seen that shortening the dosing interval and giving the drug more frequently (Oral regime B) may result in toxic plasma levels. Furthermore, a decrease in the dosing frequency could result in a subtherapeutic effect.

Choice of dosing interval is therefore extremely important in achieving and maintaining therapeutic effectiveness with minimal toxicity.

Metabolism

Most drug metabolism occurs in the liver, but can occur elsewhere, for example in the lungs and kidneys. The end result is inactivation of the drug. The enzymatic processes involved in drug metabolism are described as phases I and II.

Phase I involves chemical alteration of the basic structure of the drug by a number of versatile groups of enzymes in the liver, one of the most important being

Figure 33.3 Achieving steady state concentration following initiation of oral therapy.

Figure 33.4 Drug concentration in plasma/tissue following change in dosing schedule.

cytochrome P-450. Cytochrome P-450 consists of a large number of genetically related enzymes. (The name is derived from the fact that a light wavelength of 450 nm is absorbed by the enzymes.) Where a patient is on two or more drugs, competition between the drugs for attachment to cytochrome P-450 can result in a rise in the concentration of one of these drugs to a toxic level.

This problem has been experienced in ENT in the past, due to a practice of coprescribing antihistamines, such as terfenadine, with macrolide antibiotics, such as erythromycin. Erythromycin competes with terfenadine for a binding site, and will then inhibit the isoenzyme within the P-450 system that degrades terfenadine. This leads to toxic levels of terfenadine resulting in a characteristic pattern of ventricular tachycardia known as torsades de pointes, which is potentially fatal.

Phase II metabolism introduces hydrophilic molecules to the drug resulting in end products which are water soluble and can more easily be eliminated from the body.

Drug elimination

This overwhelmingly takes place through kidney excretion. Minor routes include lungs, breast milk, sweat and tears.

Pharmacodynamics and clinical practice

Pharmacodynamics are the key factor in determining which drug and dosing schedule to prescribe. When a drug is administered, it enters the pharmacokinetic process and eventually reaches its target tissue. The next stage, the pharmacodynamic stage, will lead to a therapeutic effect. This stage involves attachment of the drug to receptors. Receptors are proteins situated either in the cell membranes or within the cellular cytoplasm of target organs. For each receptor there is a specific group of

ligands (either drugs or endogenous substances) that can bind to the receptor and produce pharmacological effects.

There are two types of ligands of interest in ENT prescribing – agonists and antagonists. Agonists are ligands that bind to a receptor, stimulate it and produce a response. The drugs ephedrine and hyoscine are examples. Antagonists are ligands that bind to a receptor and thereby prevent an endogenous agonist from binding to and stimulating the receptor. The drugs ipratropium bromide and cetirizine hydrochloride are examples.

The intensity of the therapeutic response that drugs produce, through agonist or antagonist activity, can be plotted against the dosage. Most drugs produce graded dose-related effects and **Figure 33.5** is a dose–response curve for two similar analgesics (A and B) used in clinical ENT practice.

There are a number of important points to note in the figure.

- A log conversion is used for dosage to allow a greater range of dosage to be represented.
- There is a straight line relationship between log dose and response over a large part of the curve which allows easier comparison of drugs with similar therapeutic actions.
- There is a ‘therapeutic range’ within which most patients will achieve a therapeutic effect. The recommended dosing schedule for drugs is based on the median effective dose or ED_{50} , which is the dose effective for 50 percent of the population studied. For drug A, the therapeutic range is between 8 and 25 mg and the ED_{50} is 15 mg.
- There is a ceiling effect represented by the plateau, beyond which increasing the dose achieves no increase in the therapeutic effect.
- The potency of a drug, a term often used by pharmaceutical companies in their marketing, describes where the curve lies along the x-axis. So, in **Figure 33.5**, drug A is more potent than drug B: less

Figure 33.5 Dose response curves for analgesic drugs A and B.

of A is needed for a given therapeutic effect. A difference in potency is not an important issue in itself, unless the actual volume or mass to be given is so large that it causes difficulty in administration, or the drugs differ significantly in cost.

- The therapeutic index is a measure of the safety of a drug. It is the ratio of the dose producing the desired therapeutic effect, to the dose which produces a toxic effect. A low therapeutic index indicates a potentially dangerous drug. In **Figure 33.5**, the therapeutic index is represented by the slope of the curve. If the slope is steep, then increasing the dosage by a small amount can increase the effect to levels where toxic side effects can occur.

We have now seen how a drug formulation and drug pharmacokinetics affect the bioavailability and how pharmacodynamics relate to a therapeutic response. The next step in the therapeutic process is to monitor the therapeutic response.

Pharmacogenetics

From the previous discussion on pharmacokinetics and pharmacodynamics, it can be seen that the resultant therapeutic response to a drug could be modified by genetic factors at many different stages of the pharmacological process, from transit through the body to effector action. Sensitivity to succinyl choline is one example of an inherited autosomal recessive trait. Administration of this drug during anaesthesia in patients carrying this trait can lead to prolonged periods of apnoea, which may result in unplanned mechanical ventilation. In these patients, the cholinesterase enzyme which converts succinyl choline to succinyl monocholine has altered properties resulting either in an unexpected

sensitivity to the drug or on occasions an abnormal resistance to its effects. Biochemical variations can occur unpredictably with many drugs, giving rise to occasional idiosyncratic responses. Often these genetic variations are undetected and the effects misinterpreted.

MONITORING OF DRUG THERAPY

Once a drug regime is decided and treatment is underway, it is important to monitor the effect of the treatment and provide feedback to the patient. As well as gauging the therapeutic effect of the drug, monitoring is essential to identify adverse drug reactions.

Methods of monitoring

These fall into one of three categories.

1. **Physical monitoring.** Certain medical problems lend themselves to serial physical measurements to assess the effects of treatment, for example blood pressure in hypertensive patients, forced expiratory volume in asthmatic patients or the extent of nodal disease in lymphoma.
2. **Patient self-monitoring.** This is probably the most common type of monitoring in use in ENT practice. Patients report back on their changing symptomatology following a trial of therapy. Because such reports are subjective, problems arise in quantifying the improvement or deterioration in symptoms. It is therefore often difficult to decide whether change of dosage is required unless the expected outcome of therapy is the complete alleviation of symptoms. Short of this aim, using a written record of a problem

list and setting intermediate goals for therapy can be of help.

3. **Plasma concentration monitoring.** This method gives objective measurements of the bioavailability of the drug and reflects the tissue concentration. In clinical practice, such monitoring is important mainly for those drugs with a low therapeutic index (that is, a high risk of toxicity). Examples include aminoglycosides, antiarrhythmics, cytotoxic therapy and anticoagulants. Plasma monitoring is also used in cases of therapeutic failure, for example anticonvulsant treatment, to establish an objective level of compliance with the treatment regime. It can be used in a medicolegal context to ascertain the plasma level of recreational or illegal drugs, and is of course essential during clinical pharmacological trials.

Monitoring and compliance

Meaningful monitoring of the therapeutic effect of a drug depends on the compliance of the patient. In clinical terms, compliance is defined as the extent to which a patient's actual history of taking medication corresponds to the prescribed treatment.⁴ Many factors are involved in noncompliance. They include failure to take a prescription to the pharmacy, failure to follow the doctor's instructions, taking an incorrect dose, taking the medication erratically, stopping the treatment too early or even failure to attend for follow-up appointments. Whatever the factor, noncompliance or poor compliance is a constant and complex issue which causes major problems in the delivery of health care.

Noncompliance adversely affects:

- the clinical outcome of prescribed regimes;
- the effectiveness of healthcare budgets;
- the conclusions drawn from clinical research, especially drug trials.

The rational prescription of medication is the most common intervention in primary care and thus forms a large part of the health care costs. Poor compliance with prescribed treatment can have a major impact on clinical outcome, especially if the drug is needed to maintain vital physiological functions. This pattern is often seen with cardiac or hypertensive medication. It is also a problem in established preventative health care programmes, for example aspirin for patients with atherosclerotic disease.

Drug trials rely on an intention-to-treat analysis and unless specifically structured, do not reliably account for the effects of poor compliance. Thus results are analysed on the basis of the treatment to which the patients were assigned, regardless of whether the drugs were actually taken. This approach has created a number of problems, including biased estimates of the effectiveness of some drugs. Compliance is difficult to measure, but studies

suggest that poor compliance is to be expected in 30–50 percent of all patients, irrespective of their disease or prognosis.^{5,6,7} If this extrapolation were applied to drug trials, then the sample size would often need to be increased five-fold in order to yield the same number of 'complying' patients as for a sample where 100 percent compliance is assured.

Numerous methods of measuring compliance have been introduced, such as patient diaries and blister packs. These depend on the patient being motivated and truthful. Newer methods such as microelectromechanical systems (MEMS) are at present used only during research trials. MEMS are devices containing microchips which are attached to a bottle and are stimulated on opening the bottle. They record the number of times the patient opens the bottle – not necessarily when the patient takes the medication. Although much research has been carried out on compliance over the last three decades, no single factor or group of factors has emerged as the dominant influence on compliance. Therefore, few if any changes introduced into therapeutic regimes have led to a significant improvement in compliance. One of the reasons for the lack of progress in compliance research may be the difficulty in achieving meaningful input from patients themselves.⁸

Factors affecting compliance

NATURE OF THE TREATMENT

It has been shown that poor compliance is related to the duration of the treatment, with long-term therapies being most problematic. Other factors related to low compliance are the number of medications prescribed and the frequency of administration. The more frequently patients have to take a drug, the less likely they are to take it, and the more drugs they are prescribed the lower the overall compliance.⁹

THE TYPE OF ILLNESS

Low compliance is universally associated with psychiatric disorders and the more symptoms reported, the lower the compliance. Elderly patients with memory disorders have difficulty following complex instructions and this contributes to poor compliance. Disability can also be a factor, with patients finding difficulty in managing tablet containers. On the other hand, high compliance is found in patients who are severely disabled, and in young children, probably due to increased supervision by health care workers and parents.

BEHAVIOURAL ISSUES

Patients have been shown to have poor compliance if they are unsure about their diagnosis, if they are

asymptomatic, if there is a significant time lag between taking the drug and its effect, or if they fear the adverse effects. There may also be social or physical reasons why they do not pick up their medication from the pharmacy – for example, financial difficulties or mobility problems – in addition to the everyday inconveniences involved in carrying or taking medication.

BEHAVIOUR OF THE DOCTOR

Compliance appears to be related to the quality of the interaction between the patient and the doctor. The enthusiasm and confidence with which treatment is prescribed has been shown to influence compliance, as does the frequency of interaction and the duration of medical appointments.

Methods of improving compliance

Research has shown that compliant patients generally have better clinical outcomes than noncompliant patients. Therefore measures aimed at improving patients' understanding of their illness, their treatment and their doctor's instructions, should improve compliance.

Supervised administration of tablets and practical aids, such as blister packs and dosage counters, do help to improve compliance.

It is advisable to develop a menu of compliance-enhancing strategies that can then be tailored to the individual patient. Examples include:

- involving the patient in determining the treatment goal;
- reducing the complexity of the treatment;
- tailoring the treatment to the patient's lifestyle;
- using reminders to the patient;
- encouraging family support;
- informing the patient about possible side effects;
- monitoring compliance;
- giving the patient feedback.

The patient's input is now considered such an important aspect of compliance that the Royal Pharmaceutical Society of Great Britain has changed its terminology from compliance to concordance.¹⁰ At the centre of the concordance model is the patient as decision maker, with professional support forming a cornerstone of the medical treatment.

ADVERSE DRUG REACTIONS

Adverse drug reactions are 'unwanted effects of drugs occurring at therapeutic doses'. They may be due either to toxic effects or to side effects. A toxic effect is an adverse effect that arises because of an exaggeration of the therapeutic action and is therefore dose related. A side effect is an adverse effect that arises through a

pharmacodynamic action other than that which produces a therapeutic effect; such effect may or may not be dose related. It is estimated that up to 5 percent of hospital admissions per year are due to adverse reactions, mostly dose related.^{11,12} [****] More than 10,000 hospital beds in the UK are constantly occupied by sufferers, at a cost to the National Health Service (NHS) of up to £1 billion per year.

Adverse drug reactions can be classified as:

- non-dose related;
- dose related;
- long-term effects;
- drug interactions.

Non-dose-related adverse reactions

These are caused by allergic responses to drugs and are unrelated to the drug's therapeutic action or dosage. The ability to mount an allergic response may be inherited or may arise spontaneously. Allergic reactions are subdivided into four types:

1. **Type 1 reactions (anaphylactic):** The drug couples to cell-bound IgE leading to release of immune mediators. Type 1 reactions are caused by antibiotics such as penicillin, nonsteroidal antiinflammatory drugs such as indomethacin, plus other chemicals such as iodinated contrast media used in radiography.
2. **Type 2 reactions (cytotoxic):** The drug engages with a protein on the surface of cells, in particular hepatocytes and blood cells. Together they form a surface antigen which attracts and binds circulating IgE or subclasses of IgG, resulting in complement fixation and cell lysis. Examples of drugs causing this reaction are penicillin, heparin and methyldopa.
3. **Type 3 reactions (immune complex):** The drug binds directly to circulating IgG or IgM. The resulting immunoglobulin–drug complex becomes trapped in small capillaries, causing release of complement with destruction of the underlying capillary endothelium. Drugs causing type 3 reactions include penicillin, aspirin and cephalosporins.
4. **Type 4 reactions (cell mediated):** The drug binds to Langerhans or dendritic cells in the skin. Together, they sensitize T lymphocytes resulting in an inflammatory response. Examples are contact dermatitis due to latex, topical antibiotics or antifungal drugs.

PSEUDOALLERGIC REACTIONS

'Pseudoallergy' is a term applied to reactions that clinically resemble allergic reactions, but for which no underlying immunological basis can be currently

established. For example, aspirin and nonsteroidal anti-inflammatory drugs can trigger asthma attacks in patients who have coexisting nasal polyposis and asthma.

Dose-related adverse reactions

Dose-related adverse reactions are a consequence of the drug's normal therapeutic effects. They may be due to inaccurate prescribing or to inadvertent administration. They may on occasions result from a change in the generic formulation of a drug which can in turn lead to an increase in its bioavailability. This can be critical for drugs with a low therapeutic index and can be a risk when using different generic formulations. An example occurred in Australia with the drug phenytoin. The drug diluent was changed from calcium sulphate to lactose, resulting in toxic effects and death.

Dose-related adverse reactions can also be related to pharmacokinetic or pharmacodynamic variation among individuals. Such variation can be genetic in origin, as seen in a Gaussian distribution, where some patients display toxic effects with even a small 'normal' dose of a drug.

Variation in patients' responses may also be caused by disease such as cirrhosis or by environmental factors such as smoking, diet or alcohol consumption.

Long-term therapy causing adverse reactions

Some drugs cause adverse reactions which only develop after a prolonged period of treatment. The adverse reaction may or may not be reversible on stopping the treatment. For example, a patient may develop drug tolerance. This is a state of decreased responsiveness to a drug and can be seen following prolonged application of ephedrine nasal drops. Ephedrine causes release of noradrenalin from sympathetic nerve endings but leads to its depletion in prolonged treatment. Another example is the development of abnormal facial movements with neuroleptic drugs, such as chlorpromazine. Both these reactions are reversible on stopping the drugs.

Some long-term therapies result in irreversible adverse reactions. A well-known example is hypothyroidism occurring many years after treatment with radioactive iodine. Other irreversible adverse effects are more serious, for example, the increased risk of bladder cancer in patients taking cyclophosphamide.

Adverse reactions caused by drug interactions

When two drugs are present one may alter the effects of the other and the interaction may produce an adverse drug reaction. Drug interactions are responsible for about 7 percent of all adverse drug reactions. The drugs most likely to produce harmful interactions are those with a steep dose-response curve and therefore a low therapeutic

index. The adverse reactions may arise from many different causes, such as stimulation or inhibition of metabolism, as in the case of terfenadine and erythromycin (see above under Metabolism) or through altering renal function, thereby effecting drug elimination.

DRUG PRESCRIBING IN SPECIAL TREATMENT GROUPS

Drugs are prescribed because of their potential to benefit the patient, but in every case this is accompanied by the risk of adverse effects. This risk is greater during certain stages of life: pregnancy, childhood, old age and also in certain diseases such as hepatic or renal failure.

Pregnancy

In pregnancy, total body water increases by 6–8 L, resulting in a fall in the concentration of plasma albumin. For drugs that bind to albumin (such as anticonvulsants) the result is an increase in the free drug fraction. At the same time, the high level of endogenous progesterone during pregnancy stimulates hepatic enzymes and renal blood flow increases, which can lead to rapid clearance of drugs excreted by the kidney. In addition, there is a risk to the foetus from drugs crossing the placenta, leading to spontaneous abortion, foetal abnormalities or behavioural abnormalities.

Neonatal, infancy and childhood

In the neonatal and infancy period, major physiological changes take place in the respiratory, cardiovascular and renal systems which have important implications for drug therapy. The childhood period lasts from 1 to 12 years, and when prescribing drugs for children it is important to remember that they are not 'miniature adults'. Research suggests the incidence of adverse drug reactions occurring in hospitalized children is as high as 9.5 percent.^{13, 14}

Old age

Equally, in later years, there is a pattern of change in the physiological functioning of the body with age which can affect drug pharmacokinetics and pharmacodynamics. Greater numbers of drugs are prescribed in the elderly and the resulting polypharmacy increases the risk of drug interactions. If there is a concomitant disease such as hepatic or renal failure, then drug pharmacology is even further affected due to decreased metabolism and elimination. These cumulative factors can have profound results: it has been estimated up to 18 percent of deaths in the elderly are related to adverse drug reactions.¹⁵

Renal and hepatic failure

The treatment of patients with renal or hepatic failure is outside the scope of this chapter. It is important to recognize that the kidney is often a major determinant of drug kinetics, drug efficacy and drug toxicity. Renal function must be considered in the planning of any therapeutic strategy. As discussed above, the liver plays a major role in the pharmacodynamics of almost all drugs. In the event of liver failure, the metabolism of a drug may be radically altered, resulting in toxic levels, leading to adverse effects. Liver function must be taken into consideration when prescribing and appropriate rational therapeutic strategies implemented.

KEY POINTS

- The drug prescription should
 - maximize clinical benefit;
 - maximize patient well-being;
 - achieve lowest toxicity;
 - achieve lowest cost.
- The method of administration of a drug is the major determinant of drug bioavailability at the target organ.
- The plasma half-life of a drug determines the dosing frequency.
- The choice of dose interval is important in achieving and maintaining a steady state of therapeutic effectiveness and minimal toxicity.
- Most drugs are metabolized in the liver.
- Virtually all drugs are excreted via the kidney.
- If a drug has a narrow therapeutic range, ineffective dosing or drug toxicity are more likely to occur.
- The recommended dosing schedule for a drug is based on the median effective dose for 50 percent of the population, the ED₅₀.
- Poor compliance with prescribed treatments has a major negative impact on clinical outcomes.
- A therapeutic concordance model places the patient at the centre, as a decision maker, with surrounding professional support.
- Adverse drug reactions account for 5 percent of all hospital admissions.

Best clinical practice

- ✓ In monitoring the effect of a drug, the use of a written symptom list and the setting of intermediate treatment goals can be effective.

- ✓ The quality of the interaction between patient and doctor has a significant effect on prescription compliance.
- ✓ A menu of compliance-enhancing strategies should be devised for individual patients.

Deficiencies in current knowledge and areas for future research

- In clinical practice, ENT surgeons use a range of oral medication, topical medication, sprays, drops and inhalers. Thus, for ENT, the mechanisms of drug administration and drug absorption are particularly important. However, fundamental absorption issues such as the patterns of the mucosal distribution of nasally administered drugs, both in health and disease, are still incomplete.
- Further study may lead to improvements in the delivery systems for drugs to the nasal mucosa, with enhanced absorption and clinical effect.
- Patient compliance with prescribed medication and the related issue of the identification and recording of adverse drug reactions are problems shared by all medical specialities, but progress on specific ENT solutions to these problems should be sought.
- Respiratory medicine, ophthalmology and ENT all share the need for better mechanisms to assess the dose delivery of sprays, drops and inhalers. More work is required before reliable, effective and affordable mechanisms can emerge.
- The next edition of *Scott-Brown's otorhinolaryngology, head and neck surgery* may well see progress in:
 - mapping the distribution and absorption of nasal drugs in health and disease;
 - understanding the factors affecting patient compliance and identifying proven strategies for improvement;
 - progress towards an effective and comprehensive reporting system for adverse drug reactions (ADR);
 - the continued development towards optimal drug delivery systems for ENT mucosal administration.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words corticosteroids and the specific diseases cited throughout the text.

PHARMACODYNAMICS

Corticosteroids (CS) are small, lipophilic molecules that readily diffuse across the cell membrane into the cytoplasm, where they bind to the glucocorticoid receptor.¹ The CS–glucocorticoid receptor complex interacts with proteins that serve as transcription factors. This results in a reduced synthesis of inflammatory cytokines and subsequently in a reduced number and activity of inflammatory cells in inflamed tissue. Due to this mode of action, there is a time delay between the administration and the clinical activity of CS. However, studies have shown that the clinical effect of an intranasal CS starts as early as three hours after application.²

The density of CS molecules at receptor sites in the surface epithelium, lamina propria, blood vessels,

circulating cells and the bone marrow varies markedly between topically and systemically administered drugs. This difference in target cell accessibility to CS has an influence on the effect of topical versus systemic therapy. In the nose, for example, topical treatment is most effective on itching and sneezing, while systemic treatment is most effective on blockage and anosmia.

PHARMACOKINETICS

Intravenous corticosteroids

One hour is gained when a CS is given intravenously instead of orally. Methylprednisolone or dexamethasone are preferred, as they have a minimal mineralocorticoid

effect. When adrenal insufficiency is suspected in a patient on long-term oral treatment, hydrocortisone is the drug of choice.

Oral corticosteroids

Prednisolone is, in principle, preferred to prednisone, which is an inactive prodrug, metabolized to prednisolone in the liver. Dexamethasone is more potent and has minimal mineralocorticoid effects.

Intramuscular depot-injection of corticosteroids

When a depot-injection, e.g. methylprednisolone acetate, is given the maximum CS effect on the hypothalamic–pituitary–adrenal (HPA)-axis, measured by its effect on the plasma cortisol level, occurs after three days and the effect lasts for up to three weeks.³ The CS dose in one injection of 80 mg methylprednisolone corresponds to about 100 mg prednisolone orally.

Intranasal corticosteroids

When an aqueous spray is used, 50 percent is deposited in the nostril and in the nonciliated anterior part of the nose, while 50 percent will reach the ciliated mucous membrane, where it is either absorbed or removed by mucociliary clearance within 30 minutes.⁴ Intranasal CS are not deactivated locally and it has to be assumed that the active drug is also absorbed once it reaches the inflammatory cells. Thus, only the dosage which has been absorbed to the nasal mucosa will have an antiinflammatory effect. The measured bioavailability, demonstrated by routine tests, depends upon the CS molecule used. Highly lipophilic molecules, such as fluticasone propionate and mometasone furoate, have a large tissue distribution volume, while less lipophilic molecules, such as beclomethasone dipropionate and budesonide, are quickly absorbed into the circulation.⁵ Consequently, highly lipophilic drugs have a long elimination time, while the less lipophilic drugs have a shorter elimination time. Use of these drugs for 10–30 years has shown that both types of drug have a minimal systemic effect without a risk of clinical side effects, when used once daily in the morning at the recommended dosage.

SIDE EFFECTS

Systemic corticosteroids

The side effects from long-term systemic CS therapy are well known. However, side effects following treatment for

two to three weeks are few and minor,³ unless treatment is given to patients with diabetes or glaucoma.

Intranasal corticosteroids

When nasal CS is first sprayed into a hyperreactive nose, it can result in sneezing. Patients should be encouraged to continue treatment, as this symptom usually disappears after a few days.⁶ The condition is more a symptom of the disease than a true side effect.

A sensation of dryness in the nostrils, associated with slight blood-stained crusts, is frequently encountered, but it does not seem to worsen during long-term treatment. Usually patients can continue therapy if they reduce the dosage, use the medication only once daily and use a neutral lotion in the nostril. The patient should be told to return for examination if frequent bleeding or crusting develops. Rarely, treatment has to be temporarily stopped because of epistaxis. In very rare cases, a septal perforation can develop during treatment.⁷

Studies have shown that long-term treatment with an intranasal CS has no effect on the growth rate in children, when the drug is given once in the morning in an ordinary recommended dose, i.e. half the adult dose.^{8,9} However, one study has indicated a slight effect on growth, when a high adult dose is given twice daily.¹⁰ Long-term studies of inhaled CS have shown that although there might be a temporary growth inhibition, the children will reach normal final height.¹¹ Consequently, the risk of a reduced final height from correct nasal medication seems negligible.

Theoretically, even a small systemically active dose of CS, given for a prolonged period of time, may give an increased risk of osteoporosis and cataract. Although studies have not shown such adverse effects from intranasal CS treatment,¹² a small risk cannot be completely excluded.

Corticosteroid ear drops

There is no risk of systemic side effects from this very small CS dose. It is unknown whether ear drops can reach the middle ear mucosa and whether this implies a risk of side effects, but it seems highly unlikely. Theoretically, long-term use may cause atrophy of the skin in the external ear canal.

ALLERGIC RHINITIS

As rhinitis is a disease confined to 0.1 percent of the body weight, local intranasal treatment is, in principle, preferable to systemic treatment.

Intranasal corticosteroids

Since the introduction of beclomethasone dipropionate in 1973, a series of other molecules has been developed and marketed (flunisolide, budesonide, fluticasone propionate, mometasone furoate, triamcinolone acetonide). As these drugs do not differ significantly with regard to effect and risk of side effects, it is recommended to choose the cheapest drug. The drug is usually given as an aqueous spray. In some countries, budesonide is also available as a powder (Turbuhaler) and fluticasone propionate as nose drops.

The clinical effect has been demonstrated in more than 100 placebo-controlled studies.^{13, 14, 15, 16} [****] The effect on the nasal symptoms is pronounced. It begins after a few hours and the maximum effect is achieved after several days. When treatment is stopped, the effect disappears over a number of days.

The effect is equally good on all nasal symptoms (sneezing, rhinorrhea, blockage). A series of placebo-controlled studies has clearly shown intranasal CS to be more effective on nasal symptoms than oral and intranasal antihistamines, especially on nasal blockage.^{17, 18} [****]

Treatment is usually started with a daily dose equivalent to 400 µg beclomethasone dipropionate in an adult. When control of symptoms has been achieved, dose reduction can be attempted. A study has shown that even 64 µg budesonide is more effective than placebo.² In some patients, continuous treatment can be replaced by periodic treatment for two to four weeks.¹⁹

Some physicians are reluctant to prescribe topical nasal CS in children because of concern about long-term systemic and local adverse effects. However, used for 30 years, topical nasal CS have resulted in virtually no adverse reports. Consequently, these agents may be used in children with persistent moderate to severe allergic rhinitis, particularly when nasal blockage is a pronounced symptom. The dosage is half the adult dose or less and the medication is given once daily in the morning. In our opinion, allergic rhinitis in children is more often undertreated than overtreated. It is the task of the clinician to balance the minimal theoretical risk of side effects against the increased quality of life for a child who can breathe again through the nose and be rid of disturbing itching, sneezing and runny nose.

Pregnancy is not a contraindication as intranasal CS treatment has not been associated with any teratogenic or adverse effects. However, as there are no adequate and well-controlled studies in pregnant women for any drug, treatment should be used only if the expected benefit justifies the potential risk to the foetus.

Systemic corticosteroids

Treatment can be given to adults either orally or as an intramuscular injection of a slow-release formulation.

There is no reason to believe that these two therapies have different therapeutic indices.

Surprisingly, there is only a single placebo-controlled study of oral CS (three different doses of methylprednisolone given three times daily). The study showed an effect on nasal blockage at 6 mg (equipotent to 7.5 mg prednisolone) and on blockage and rhinorrhoea at 24 mg (30 mg prednisolone).³ [***/**] Three placebo-controlled studies of a depot-injection have shown a marked effect on nasal blockage, lasting for more than four weeks, but merely a mild to moderate effect on sneezing and rhinorrhoea.³ [***]

The treatment can be added, when an intranasal CS is insufficient. However, there are no studies to demonstrate added efficacy of these two types of CS administration. [*] The optimum dose of oral CS is not known. The CS dose of a depot-injection (e.g. 80 mg methylprednisolone acetate) corresponds to 100 mg prednisolone.

Systemic CS treatment should not be given to children, pregnant women or to patients with diabetes mellitus, severe osteoporosis, glaucoma or cataract.

The risk of side effects from a short-term, two- to three-week treatment is very small and should be balanced against the benefits of therapy.

IDIOPATHIC RHINITIS (PERENNIAL NONALLERGIC NONINFECTIOUS RHINITIS)

It is more difficult to treat perennial rhinitis than simple hay fever. Tarlo *et al.*²⁰ found that only 54 percent of patients with perennial rhinitis achieved acceptable symptomatic improvement from a CS spray. However, after administration of short-term oral prednisone, 73 percent of the patients obtained moderate or marked symptomatic improvement from topical treatment. In severe cases, it would be advisable to conduct a therapeutic trial with short-term systemic CS, when the effect of nasal CS is insufficient.

In patients suffering from idiopathic rhinitis, intranasal CS have shown a significant effect in most,^{20, 21, 22, 23} but not in all studies.²⁴

The general impression, supported by a few small studies,^{25, 26} is that the treatment is particularly effective when nasal eosinophilia is present. However, a recent large study of idiopathic rhinitis has shown equal efficacy in patients with and without nasal eosinophilia.²³ While the effect is marked in patients with eosinophil-dominated inflammation and intolerance to acetylsalicylic acid,²⁷ the effect in other cases of idiopathic rhinitis cannot be predicted. It would be advisable to conduct a one-month therapeutic trial with intranasal CS in all patients with persistent idiopathic rhinitis. [***]

RHINITIS MEDICAMENTOSA

A placebo-controlled study of topical CS in rhinitis medicamentosa has shown that patients on intranasal CS have a faster onset of symptom reduction and of improvement of mucosal swelling,²⁸ indicating that an adequate treatment of such patients consists of a combination of vasoconstrictor withdrawal and a topical CS to alleviate the withdrawal symptoms. Another study has shown an effect of intranasal CS on oxymethazoline-induced rebound congestion.²⁹ A short course of intranasal CS is recommended, when a vasoconstrictor is withdrawn. [***]

INFECTIOUS RHINITIS (COMMON COLD)

The common cold is a virus-induced inflammation, characterized by neutrophil accumulation in the nasal mucous membrane. Theoretically, a clinical effect could be expected from an antiinflammatory CS. However, at least two placebo-controlled trials have failed to show any effect.^{30,31} Thus, CS are highly effective in eosinophil-dominated inflammation and allergy, but not in neutrophil-dominated inflammation and infection. CS are not recommended for the treatment of common cold. [***]

NASAL POLYPOSIS

The aetiology of nasal polyps is unknown. Eosinophils are commonly found in polyps, but the association with allergy appears to be coincidental. Topical CS treatment reduces nasal symptoms, polyp size and the number of recurrences after polypectomy. [****] A short course of systemic CS may help combat obstruction, improve intranasal spray distribution, improve the sense of smell and facilitate intranasal surgery. [***] Management of patients with severe polyposis is still unsatisfactory but it has been improved by the combination of long-term topical CS, short-term systemic CS and surgery, as described in Chapter 121, Nasal polyposis.

HYPOSMIA AND ANOSMIA

Hyposmia is a common finding in patients with allergic rhinitis, especially when the disease is chronic. Severe hyposmia or anosmia frequently occurs in nasal polyposis. While intranasal CS treatment has a beneficial effect on this symptom in allergic rhinitis, the effect in polyposis is poor. Systemic CS are invariably effective, but the effect is short-lasting.³²

A short course of systemic CS can be used occasionally, when olfactory dysfunction impairs the quality of life in

patients with nasal polyposis and when it is indicated to make a distinction between a potentially reversible (rhinitis, polyposis) and an irreversible (viral respiratory infection, toxic chemical exposure, head trauma) olfactory dysfunction. [***]

SINUSITIS

Clinically it is difficult to define sinusitis, especially in those patients with chronic disease where a distinction needs to be made between the symptoms of rhinitis and those of sinusitis.³³ Information received from studying the patient's symptoms and the imaging examination may not agree. Based on a CT scan, a simple common cold is, as a rule, sinusitis, and patients with nasal polyposis invariably show sinusitis on imaging, whether they have sinusitis symptoms or not.

In patients known to be steroid responders, an antirhinitis effect may masquerade as an antisinusitis effect. Therefore, the inclusion of some steroid responders (nasal polyposis, perennial eosinophilic rhinitis, acetylsalicylic acid intolerance) in sinusitis studies may give a false-positive result.

While a few small studies of intranasal CS treatment of acute exacerbations in patients with chronic recurrent sinusitis have been negative,^{34,35,36,37} two recent large placebo-controlled studies have been more positive, showing a significant effect on symptoms, but not on imaging.^{38,39}

At present, an unqualified recommendation for the use of intranasal CS treatment for chronic recurrent sinusitis cannot be made. However, a therapeutic trial for three months could be made in selected patients. [***]

As a nasal spray will not reach the sinuses nor the middle meatus, with the openings to the paranasal sinuses, it seems possible that a short course of systemic CS may be effective, but placebo-controlled studies have not been performed. [*]

In conclusion, many clinicians believe that intranasal CS are important in the treatment of sinusitis. However, only scant controlled studies support this conjuncture and the use of CS remains controversial.

ANGIOEDEMA

Due to their antiinflammatory and antioedema effects, systemic CS, in conjunction with epinephrine and antihistamine, are generally used in the treatment of angioedema involving the mouth, throat and the upper respiratory tract⁴⁰ and as such should be considered an acceptable treatment.⁴¹ However, this practice is not supported by any placebo-controlled study, which are unlikely to be undertaken. [**/*]

ADENOIDS

Lymphocytes are sensitive to CS and, by mucociliary clearance, a nasal spray will be carried to the adenoidal region. There has been only one placebo-controlled study of intranasal CS treatment of children with adenoidal hypertrophy. This study, involving only 17 children, showed a highly significant and long-lasting effect on both adenoid/choanal ration and symptom scores.⁴² Further studies are warranted before this treatment can be recommended. [***/**]

PHARYNGITIS

A single placebo-controlled study of an intramuscular CS injection has shown an improvement of pain score in adults with severe pharyngitis.⁴³ However, in our opinion, this does not justify the use of CS in pharyngitis in general, but it may be tried in selected cases with severe and threatening oedema, compromising breathing. [***/**]

EPIGLOTTITIS

There is a remarkable absence of documentation of the use of CS in acute epiglottitis. Due to the severity of this condition, placebo-controlled studies should not be carried out. However, such investigations should be undertaken, since it is common practice in intensive care units to use CS in patients with severe oedema. [*]

TONSILLECTOMY

Tonsillectomy is one of the most commonly performed surgical procedures. The effect of a single preoperative intravenous dose of CS (dexamethasone, 0.15–1.0 mg/kg) has been studied in a number of placebo-controlled trials. A recent meta-analysis of randomized studies found that the effect is clinically relevant with regard to nausea, vomiting and intake of solid food on the first post-operative day.⁴⁴ Given the frequency of tonsillectomy, the relative safety and low cost of a single injection of CS, and the reduction in postoperative morbidity, the authors recommend routine use of a single intravenous dose during paediatric tonsillectomy. In contrast to the above studies, Palme *et al.*⁴⁵ concluded that a seven-day course of CS plays a limited role in patients' recovery from tonsillectomy.

We find that the use of CS in tonsillectomy is open for debate and reference should be made to an article expounding the merits of CS use⁴⁶ and another against their use.⁴⁷ [****]

MONONUCLEOSIS

In upper airway obstruction due to infectious mononucleosis, it is tempting to resort to some antioedematous drug treatment. The use of CS in this disease is not investigated in any larger study, not to mention any meta-analysis. Tynell *et al.*⁴⁸ demonstrated that acyclovir combined with prednisolone inhibited oropharyngeal Epstein–Barr virus (EBV) replication without affecting the duration of clinical symptoms or development of EBV-specific cellular immunity, while Brandfonbrener *et al.*⁴⁹ found a more beneficial effect, although the results were not striking. Furthermore, there is one report of presumably CS-induced lethal disseminated intravascular coagulation and hepatic necrosis.⁵⁰ We must conclude that the use of CS in EBV infection is still a moot point. [**/*]

CROUP

Croup (acute laryngotracheobronchitis) is a frequent disease in children. It is characterized by hoarseness, a dry barking cough and inspiratory stridor. These symptoms occur as a result of oedema in the larynx and trachea due to a viral infection. The disease is usually benign and self-limiting, but it may be the cause of death due to sudden obstruction of the airways.

There is ample evidence from randomized, placebo-controlled trials, summarized by a meta-analysis⁵¹ that CS are effective in croup. [****] Symptoms are improved as early as six hours and for up to at least 12 hours. There is no demonstrable effect after 24 hours. Dexamethasone (orally or intramuscularly) has been evaluated in 17 trials and nebulized budesonide in nine studies.

In most studies, dexamethasone has been given as a single dose of 0.3 mg/kg. This is a high dose, corresponding to 150 mg prednisolone in an adult. However, the risk of side effects from a single dose is very small.

In mild to moderate cases, it is preferable to start treatment at home with a palatable soluble CS (e.g. betamethasone tablets dissolved in a drink). In hospitalized patients, treatment is usually given as an intramuscular injection of dexamethasone (0.3 mg/kg). If available, nebulized budesonide can be used instead (2 mg).

EXTERNAL OTITIS

The symptoms of external otitis vary considerably based on whether the otitis is caused by slight eczema or severe inflammation caused by a bacterial infection. Consequently, the standard treatment is either CS alone, antimicrobial agents alone or a combination of the two. Considering the widespread use of CS ear drops, there is a remarkable absence of placebo-controlled studies. Only one study⁵² has demonstrated a significant effect

of budesonide compared to placebo. This CS molecule is, however, not marketed as ear drops. Several animal studies have been published demonstrating the availability of an animal model for studying external otitis.^{53,54} In these studies the potency of the CS is discussed and it is most likely that the commonly used CS, hydrocortisone, is too weak to have the desired effect. Further controlled studies are needed. [**]

It is strange that perforation in the drum is listed as a contraindication for using ear drops containing CS. This must be a misconception, since litres of steroid-containing ear drops have been poured into middle ears without causing any inner ear damage, and we believe this warning is not based on solid evidence.

SECRETORY OTITIS MEDIA

secretory otitis media (SOM) is one of the most frequent diseases in childhood. The demonstration of or the rejection of the efficacy of CS is therefore of utmost importance. It is likely that the addition of systemic CS to an antibiotic treatment has a beneficial effect upon the status of the middle ear.^{55,56,57,58} On the other hand, Lambert⁵⁹ and Macknin and Jones⁶⁰ could not demonstrate any effect of either prednisone or dexamethasone.

In a Cochrane review,⁶¹ it was concluded that there is evidence that CS combined with an antibiotic leads to a faster resolution of SOM in the short term. However, there is no evidence for a long-term benefit from treating hearing loss-associated SOM with either oral or topical nasal CS. These treatments are therefore not recommended at the present time. [***]

Considering the possibility that SOM is indeed a bacterial infection, it cannot be ignored that CS inhibit the development of endotoxin-induced otitis media with effusion as demonstrated by Baggett *et al.*⁶² This adds to the confusion, but stresses the need for additional controlled studies.

ACUTE OTITIS MEDIA

From a theoretical point of view, only systemic CS administration can be taken into consideration. In children with tympanostomy tubes, who experience a bout of acute otitis media, with discharge through the tubes, a borderline effect of oral prednisolone has been suggested.⁶³ Apart from this report, there is no evidence supporting the notion that CS are of any value in the treatment of this disease entity, and such treatment is not to be recommended. [**/*]

CHRONIC OTITIS MEDIA

As with acute otitis media, evidence for supporting the notion that CS have a place in the treatment in chronic suppurative otitis media is scarce. Using monkeys inoculated with *Pseudomonas aeruginosa* in the middle ear, it was found that dexamethasone enhanced the efficacy of tobramycin,⁶⁴ whereas a 0.2 percent solution of ciprofloxacin was as effective as a combination preparation with CS.⁶⁵ Further placebo-controlled studies are needed to shed light on this issue, and for the present time CS treatment in suppurative otitis media is not recommended. [**/*]

SUDDEN DEAFNESS

Sudden deafness or idiopathic sudden sensorineural hearing loss (ISSNHL) is an abrupt sensorineural hearing loss of at least 30 dB in at least three contiguous audiometric frequencies, variably defined as developing in 12 hours or less,⁶⁶ 24 hours or less⁶⁷ or in 3 days or less.⁶⁸ In making the diagnosis of ISSNHL, identifiable causes of hearing loss should be excluded and the patient should not have a history of previous fluctuations of hearing. The most commonly proposed hypotheses for the aetiology of ISSNHL include disturbance of labyrinthine blood circulation, subclinical viral labyrinthitis, spontaneous labyrinthine membrane rupture and autoimmune pathogenesis.⁶⁷ Among the postulated aetiologies of ISSNHL, autoimmunity and perhaps viral infection may be ameliorated by steroids.

The documentation for an effect of CS is poor. A number of publications claim a beneficial effect of CS,^{69,70,71,72} while others have come to the opposite conclusion.^{73,74,75,76} A Medline search⁷⁷ came to the conclusion that no consensus existed on the effective treatment of ISSNHL.

At this point we will refrain from recommending systemic use of CS in patients with ISSNHL. [***/*] However, recent developments have rendered it possible to deliver CS directly at the round window membrane, resulting in a much higher concentration of CS in the inner ear fluids. Anecdotal reports show that such delivery results in hearing improvement in patients who had no benefit from systemic CS prior to the intratympanic, round window application.⁷⁸

MENIÈRE'S DISEASE

Treatment of Menière's disease is hampered by the erratic course of the disease. Oral CS is one treatment that is heralded as being effective. To date, there are no existing controlled studies proving that systemic CS have any effect upon the course of the disease. In recent years, intratympanic CS application has been suggested as an

effective treatment; however, the only existing randomized double-blind study⁷⁹ concludes that intratympanic administration of dexamethasone showed no benefit over placebo. New delivery systems are now available, resulting in a more specific delivery of the drug to the inner ear. While there are only anecdotal reports of the efficacy, we cannot rule out a possible effect. However, at the present time we cannot recommend either systemic or intratympanic use of CS in Menière's disease. [**/*]

FACIAL PALSY

Bell's palsy, also known as idiopathic facial nerve paralysis (IFNP) is the most common cause of facial paralysis. IFNP results in facial motor dysfunction, the degree of which ranges from minor weakness to complete paralysis. Treatment is aimed at improving recovery of facial function and the prevention of neural degeneration and its associated complications. Of the multiple treatment modalities evaluated over the past three decades, CS therapy has become the most widely accepted. However, despite the widespread clinical acceptance of CS therapy for IFNP, the efficacy of this therapy has not been clearly demonstrated in the literature.

In this age of meta-analysis and Cochrane database systemic reviews, the confusion about the efficacy of CS in the treatment of IFNP is striking. A meta-analysis including 47 trials⁸⁰ came to the conclusion that there is a statistically significant benefit for complete IFNP patients treated with a total prednisone dose equivalent to 400 mg or more started within seven days of onset of paresis. It is, however, remarkable among the 47 trials used to reach this conclusion that only three met the criteria for a randomized controlled trial. In contrast to this meta-analysis, a Cochrane database systemic review⁸¹ came to the opposite conclusion that the available evidence from randomized controlled trials does not show significant benefit from treating Bell's palsy with CS. More randomized controlled trials with a greater number of patients are needed to determine reliably whether there is real benefit (or harm) from the use of CS therapy in patients with Bell's palsy. Also in this review, only three trials met the requirements of a randomized controlled trial. These trials were not the same as the trials used in the meta-analysis of Ramsey *et al.*⁸⁰

We must conclude that using CS for IFNP is still a moot point and further placebo-controlled, blinded randomized studies are required before a recommendation for CS therapy can be made. [***]

SARCOIDOSIS

Nasosinal involvement is rare in patients with sarcoidosis and exceptionally rare as an isolated disease

manifestation.⁸² In the absence of controlled trials, the efficacy of CS needs to be deduced from pulmonary studies. [**]

Only five randomized controlled trials of CS treatment (prednisolone 15–40 mg/day) for pulmonary sarcoidosis were identified in a meta-analysis.⁸³ Oral steroids improved the chest x-ray, symptoms and lung function (diffusion capacity) over 6–24 months. There are no data beyond two years.

In a consensus report,⁸⁴ it was concluded that oral CS is an effective short-term therapy, but it is not known whether the treatment alters the natural history of the disease. It is recommended to start with prednisolone 20–40 mg/day. Among steroid responders, the dose is slowly tapered to 5–10 mg/day. Treatment should be continued for a minimum of 12 months.

Oral CS will probably relieve the discomfort of nasosinal sarcoidosis, but the symptoms need to be severe in order to balance the expected side effects from long-term treatment.

WEGENER'S GRANULOMATOSIS

Combined therapy with cyclophosphamide and systemic CS for remission induction in Wegener's granulomatosis is a well-established and generally recommended treatment.⁸⁵ [*] Placebo-controlled trials have not been performed.

KEY POINTS

- Corticosteroids are widely used in otolaryngology and especially in rhinology.
- Topical nasal steroids are safe and effective.
- The risk of side effects from short-term systemic steroids is small.

Best clinical practice

- ✓ Allergic rhinitis, idiopathic rhinitis and nasal polyposis are best treated with an intranasal CS, when necessary with a supplement of a short course of systemic CS.
- ✓ A short course of systemic CS can be tried in anosmia.
- ✓ The role of intranasal CS in chronic sinusitis remains controversial.
- ✓ Systemic CS are often used for angioedema and epiglottitis, but the effect is unproven.
- ✓ CS for adenoids and for pharyngitis cannot be recommended at present.

- ✓ The use of a short course of systemic CS in tonsillectomy is open for debate.
- ✓ A single dosage of systemic CS has a proven effect in croup and prompt treatment, either orally or intravenously, is recommended.
- ✓ CS ear drops alone or in combination with an antibiotic has a well-established, but poorly documented, place in the treatment of external otitis.
- ✓ A short course of systemic CS for otitis media with effusion may be helpful, but a recommendation awaits further controlled studies.
- ✓ At present, CS are not to be recommended for acute otitis media, chronic otitis media, sudden deafness, Menière's disease and facial palsy.
- ✓ Systemic CS must be used for Wegener's granulomatosis in spite of a lack of controlled evidence.

Deficiencies in current knowledge and areas for future research

- Systemic CS are often used for a variety of diseases. However, the treatment is often not evidence based and there is a striking lack of placebo-controlled studies and in particular of dose-effect studies.
- In severe allergic rhinitis, a short course of systemic CS is often used, but the optimal dosage has not been defined.
- Intranasal CS are effective in some, but not all, cases of idiopathic rhinitis. Could responsiveness be predicted by local eosinophilia or by another inflammatory marker?
- The role of intranasal CS in subgroups of chronic sinusitis needs to be defined by placebo-controlled studies. Are systemic CS effective?
- Placebo-controlled studies of intranasal CS treatment for enlarged adenoids in children are warranted.
- There are no placebo-controlled studies of the effect of systemic CS in angioedema, in epiglottitis and in mononucleosis.
- We need studies of whether more than a single dose of systemic CS is indicated in croup.
- CS ear drops alone or in combination with an antibiotic for external otitis media are remarkably poorly documented. A study with one formulation used in one ear and placebo/another formulation in the other ear would be easy to perform.
- The usefulness of intranasal and of systemic CS for otitis media with effusion needs a detailed analysis in placebo-controlled studies.

Sodium fluoride treatment in otosclerosis	434		

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words otitis externa, ear drops, antibiotics, betahistine, gentamicin, Menières, acyclovir and sodium fluoride.

INTRODUCTION

Medicines are commonly prescribed in the management of otological diseases. Whilst the efficacy of some treatments may be uncertain, it is important to understand how these drugs act, their indications, contra-indications and side effects. This chapter discusses these factors in relation to a number of specific types of otological medications.

TOPICAL EAR PREPARATIONS

Eardrops are solutions or suspensions of medicaments in water, glycerol, diluted alcohol, propylene glycol or other suitable solvent for instillation into the ear. A solution comprises a solute (drug) dissolved in the solvent whereas a suspension consists of an insoluble drug distributed in a liquid. Some preparations used in otology are also used as eye or nose drops. Since these drops are in multiple-application containers, the vehicle contains a bactericidal and fungicidal agent such as benzalkonium chloride (0.01 percent). Other adjuvants in ear and eye drops include buffers such as sodium metabisulphite and disodium

edetate. The buffers are used to maintain the pH to minimize breakdown of the active constituents or to increase comfort for the patient. Both sodium metabisulphite and disodium edetate are effective at retarding oxidation reactions and the latter can enhance the bactericidal activity of benzalkonium chloride and chlorhexidine acetate. Information on excipients contained in drops is found in the British National Formulary or its equivalent. This information is useful since some patients may be allergic to topical ear medication and this allergy may not be to the primary constituent but to the excipients.

Ear drops are dispensed in coloured fluted glass bottles with a plastic screw cap incorporating a glass dropper tube and rubber teat, or, more commonly, in plastic squeeze bottles fitted with a plastic cap incorporating a dropper device. Such containers are designed to prevent light degradation of the contents.

Some ear preparations are available as creams or ointments where the antimicrobial and/or anti-inflammatory substance is prepared in a suitable base such as liquid paraffin, wool fat and yellow soft paraffin. Both are semisolid preparations but in a cream the base is absorbed into the skin, whereas in an ointment only the medication

is absorbed from the greasy base. In general, ointments are useful in dry scaly conditions whereas creams can also be used in weeping skin conditions.

Again, warnings that the preparation contains lanolin (wool fat) are useful since some patients are allergic to lanolin.

Topical ear preparations for inflammatory and infective conditions

INDICATIONS

A number of topical ear preparations in the form of drops or ointments are available for the treatment of otitis externa and discharging mastoid cavities. Many are also used in discharging ears with a perforated tympanic membrane or ears with a grommet *in situ*. In this latter situation this is an unlicensed indication for the use of many of these preparations. Manufacturers' data sheets continue to state that even plain steroid drops are contraindicated in the presence of a perforation. In chronic suppurative otitis media, it has been shown that aural toilet and topical antibiotics, especially a quinolone, is effective in resolving otorrhoea and eradicating bacteria from the middle ear. Topical antibiotic preparations are more effective than oral preparations and the addition of oral therapy to topical antibiotics confers no greater benefit than the latter used alone (see Chapter 34, Corticosteroids in otolaryngology).¹

SPECIFIC PREPARATIONS

Acetic acid 2 percent has antifungal and antibacterial properties and can be used to treat mild otitis externa. Aluminium acetate is an astringent that can be applied as drops or onto a gauze wick. An astringent is an agent which causes shrinkage or constriction and is usually applied topically. The hygroscopic effect reduces oedema in the inflamed ear canal, opening the meatus. Aluminium acetate has a tendency to form crystals in the ear. Regular aural toilette is required to remove both the crystals that form as well as the debris produced by the inflammatory process. This treatment can be safely used in pregnancy. Boric acid has been used in the past for its weak fungistatic and bacteriostatic activity and is used as a mild disinfectant in lotions, ointments and powders in concentrations of up to 5 percent. It is absorbed through damaged skin and may cause systemic toxicity. Acute and chronic toxicity can occur, presenting with gastrointestinal disturbance, rash, central nervous system and renal involvement that may result in death. Slow excretion of boric acid can lead to cumulative toxicity during repeated use.

Some preparations contain only a steroid and are used in eczematous otitis externa. The steroid reduces inflammatory swelling and helps control irritation. The steroid stimulates the synthesis of lipocortin in leukocytes. This protein inhibits phospholipase A₂ that reduces the

formation of arachidonic acid, the precursor of many inflammatory mediators. Betamethasone sodium phosphate (Betnesol®) and prednisolone sodium phosphate (Predsol®) are steroids available as ear drops. These steroids are combined with anti-infective agents for use in the management of infected otitis externa. Other steroids found in combination with anti-infective drugs include dexamethasone (Otomize® – with neomycin and glacial acetic acid, Sofradex® – with framycetin sulphate and gramicidin), flumetasone pivalate (Locorten-Vioform® – with flumetasone pivalate and clioquinol), hydrocortisone acetate (Gentisone HC® – with gentamicin, Neo-Cortef® – with neomycin sulphate) and triamcinolone acetate (Audicort® – with neomycin undecanoate and Tri-Adcortyl Otic® – with gramicidin, neomycin and nystatin). Clioquinol (found in Locorten-Vioform) is an 8-hydroxyquinolone with both antibacterial and antifungal properties and is useful when a mixed infection is suspected. The other antibiotics included in ear preparations are framycetin sulphate, gentamicin and neomycin sulphate which are all aminoglycosides. They are bactericidal, inhibiting microbial protein synthesis and are effective against aerobic Gram-negative bacteria. Bacteria may acquire resistance via plasmids against one aminoglycoside but these bacteria rarely exhibit resistance to other aminoglycosides. This accounts for the benefit in changing the ear drops if the otitis externa fails to respond to one preparation.

Some of these preparations are available as ear sprays (Otomize) and there is some evidence that these cover the external meatus more effectively than traditional ear drops² and are easier for the elderly to apply. However, in some clinical situations, drops are more likely to reach the infected and inflamed parts of the external ear, middle ear or mastoid cavity at which treatment is aimed. Prolonged use of antibiotic/steroid preparations may sensitize the skin and may lead to fungal infections.

Clotrimazole is an azole derivative with a broad-spectrum antifungal activity that acts by inhibiting ergosterol synthesis in the fungal cell membrane. At lower concentrations, clotrimazole merely inhibits fungal growth but at higher concentrations, fungi are killed by clotrimazole action causing direct membrane damage. Increasingly, ciprofloxacin eye drops are used as ear drops in the management of *Pseudomonas* spp. ear infections. This is an unlicensed use in the UK where licensed ciprofloxacin ear drops are unavailable. Ciprofloxacin drops have been used widely in the rest of Europe, North America and beyond.

CONTRAINDICATIONS

The use of preparations containing only a steroid is contraindicated in untreated infections since the immunosuppressive effect of corticosteroids may exacerbate the infection. More controversial is the use of preparations with anti-infective agents in the presence of a perforated

tympanic membrane because of the potential for ototoxicity.

SIDE EFFECTS

The most common side effects with these preparations are hypersensitivity reactions and local irritation, burning and itching.

The use of anti-infective ear drops in the presence of a tympanic membrane perforation

The product licences do not permit the use of anti-infective ear drops in ears with perforated tympanic membranes as a result of cochlear damage that occurred when such drops were instilled into guinea pig ears.^{3,4} These authors recognize that the round window niche in humans is relatively deep and often protected by a pseudomembrane whilst in the guinea pig the round window is completely exposed. In patients with active chronic suppurative otitis media there is no evidence that the use of these ear drops causes sensorineural deafness. (see Chapter 34, Corticosteroids in otolaryngology).^{5,6,7}

Topical ear preparations for removal of ear wax

Many cerumenolytics, including oils and aqueous preparations, are available to soften wax prior to syringing or to disintegrate or disperse the wax, to avoid the need for syringing altogether. Burton and Dorée⁸ undertook a systematic review and found eight clinical trials. All had a small number of participants, and most were of poor methodological quality. The review concluded that there is insufficient evidence to favour any one particular cerumenolytic. Water and sodium chloride 0.9 percent seem to be as effective as any proprietary agent. Sodium bicarbonate 5 percent ear drops, olive or almond oil ear drops are also safe and inexpensive although their effectiveness has not been evaluated in randomized controlled trials. If the wax is impacted, these drops can be used twice a day for a few days prior to syringing. Some proprietary preparations contain organic solvents (chlorbutanol, paradichlorobenzene) that may cause irritation to the meatal skin. The rationale for inclusion of these ingredients in the preparations is not clear and the vehicle alone is often effective.

SYSTEMIC ANTIBIOTICS

Indications

Systemic antibiotics are prescribed in the otological conditions of acute otitis media (AOM), cellulitis associated with furunculosis, otitis externa and perichondritis.

In AOM, the use of antibiotics is controversial. Galsziou *et al.*⁹ found that antibiotic usage in AOM in children varied from 31 percent in the Netherlands to

98 percent in the USA and Australia. Their Cochrane review concluded that antibiotics provide a small benefit, however, since most cases resolve spontaneously, this benefit must be weighed against possible adverse reactions. Seventeen children must be treated to prevent one child from having pain after two days. Antibiotic treatment may play an important role in reducing the risk of mastoiditis in populations where it is more common. If antibiotics are used, amoxycillin appears to be the first-line treatment, with erythromycin in those who are penicillin sensitive. Should treatment fail, second-line agents include co-amoxiclav and cephalosporins.

Conservative management of acute mastoiditis (without subperiosteal abscess) has been adopted since a third of patients will settle in 24–48 hours with intravenous antibiotics.^{10, 11, 12}

Flucloxacillin is the antibiotic of choice in treating cellulitis due to *Staphylococcus*. Penicillin V is used in erysipelas due to *Streptococcus*.

Ciprofloxacin is the drug of choice in malignant otitis externa and is also used in treating perichondritis due to *Pseudomonas aeruginosa*.

Mechanisms of actions

The penicillins have a bactericidal action, inhibiting cell wall synthesis by preventing the formation of peptidoglycan cross-bridges. The penicillinase-resistant penicillins, flucloxacillin, cloxacillin and methicillin, are semisynthetic penicillins, resistant to penicillinase by virtue of an isoxazolyl group on R₁. Many bacterial β -lactamases are inhibited by clavulanic acid, and a mixture of this inhibitor with amoxycillin (co-amoxiclav) is available. The cephalosporins are also bactericidal. They contain a β -lactam ring and their mechanism of action is similar to the penicillins.

The macrolides, for example erythromycin, act by inhibiting bacterial protein synthesis. It binds to the 50S bacterial ribosome subunit inhibiting translocation.

Metronidazole was initially used in protozoal infections but was found to be very effective against anaerobic bacteria. The drug is reduced to active metabolites that interfere with nucleic acid function. Ciprofloxacin is a fluoroquinolone and acts on both stationary and dividing bacteria by inhibiting DNA gyrase, an enzyme that compresses the bacterial DNA into supercoils. Cell death is thought to occur as a result of the unwinding of the supercoils.

Antibacterial spectrum

Table 35.1 demonstrates the antibacterial spectrum of the various antibiotics. The penicillinase-sensitive penicillins have a greater spectrum of activity than the β -lactamase resistant drugs, but the combination of clavulanic acid with amoxycillin enables protection of the β -lactam ring, allowing this essential part of the penicillin molecule to remain active.

Table 35.1 The antibacterial spectrum of antibiotics.

Penicillins	Antibacterial spectrum
Benzylpenicillin and phenoxymethylpenicillin	Streptococcal, non β -lactamase producing staphylococcal, pneumococcal, clostridial infection, meningococcal, gonococcal, spirochaetes (syphilis), anthrax, actinomycosis
Ampicillin and amoxycillin	As above and <i>Strep. faecalis</i> , most <i>Haemophilus influenzae</i> and many coliforms
Methicillin, cloxacillin, flucloxacillin	Similar to penicillin but less active. Stable to staphylococcal β -lactamase
Carbenicillin and ticarcillin	Similar to amoxycillin and in addition activity to <i>Ps. aeruginosa</i> , most <i>Proteus</i> spp. and against bacteroides
Mezlocillin, azlocillin, piperacillin	Similar to ticarcillin and in addition to <i>Klebsiella</i> spp. and greater activity against pseudomonads
Mecillinam	Coliforms, little activity against Gram-positive bacteria
Cephalosporins	Antibacterial spectrum
First generation: cephaloridine, cephalothin, cephalexin, cephradine and cephalozin	Broad spectrum EXCEPT against <i>Strep. faecalis</i> , <i>Ps. aeruginosa</i> , <i>H. influenzae</i> and <i>Bacteroides</i> spp. Staphylococcus is sensitive, except for MRSA
Second generation: cefuroxime, cefamandole, cefoxitin	Broad spectrum with stability against β -lactamases. Active against <i>H. influenzae</i> and <i>Bacteroides</i> spp. but less activity against staphylococcus
Third generation: cefotaxime, latamoxef, ceftazidime, cefsulodin	As for second generation but also active against <i>Ps. aeruginosa</i>
Erythromycin	See penicillins but also active against <i>H. influenzae</i> , <i>Bord. Pertussis</i> , <i>Bacteroides</i> spp., <i>Campylobacter</i> spp. <i>Legionella pneumophila</i> , <i>Mycoplasma pneumoniae</i> and <i>Chlamydiae</i>
Sulphonamides and trimethoprim: co-trimoxazole	Broad, active against Gram-positive and -negative bacteria except <i>Ps. aeruginosa</i>
Aminoglycosides: gentamicin, tobramycin, netilmicin, amikacin, kanamycin and neomycin	Coliforms, <i>Ps. aeruginosa</i> and staphylococci; streptomycin; mycobacteria
Vancomycin	Staphylococci including MRSA, streptococci and clostridia
Tetracyclines: tetracycline, chlortetracycline, oxytetracycline, doxycycline, minocycline	Broad; Gram-positive and -negative bacteria, brucellae, <i>M. pneumoniae</i> , rickettsia, <i>Coxiella burneti</i> and <i>Chlamydiae</i> . Some resistance to <i>Strep. pyogenes</i> , pneumococci and <i>H. influenzae</i> . <i>Ps. aeruginosa</i> and <i>Proteus</i> spp. resistant
Metronidazole	Anaerobic bacteria and protozoa
Ciprofloxacin	Broad; Gram-negative bacteria including <i>Ps. aeruginosa</i> , staphylococci including MRSA, streptococci less sensitive
Monobactams: aztreonam	Narrow, active against aerobic Gram-negative bacteria (less sensitive to <i>Ps. aeruginosa</i>)

Dosage

Specific dosage recommendations can be found in the British National Formulary. Phenoxypenicillin, amoxycillin and flucloxacillin have better oral absorption than ampicillin but all should be taken at least 30 minutes before food since they are destroyed, to some extent, by gastric acid. The penicillins have good penetration to most tissues but poor entry to CSF (overcome by giving higher doses intravenously). Dosage modification is required in patients with severe renal failure.

Ciprofloxacin can achieve high concentrations in bone and soft tissue, even after oral administration. A dosage of 1.5g daily over a period of 6–12 weeks has been recommended in the treatment of malignant otitis externa.^{13, 14}

Contraindications

In all cases the prescribing of these drugs is contra-indicated when the patient is known to be allergic to the

ingredients or related compounds. Immediate hypersensitivity to penicillins occurs in 0.05 percent of patients, the severity of which ranges from urticaria or wheezing to a life-threatening anaphylactic response. Less than 5 percent of patients may develop a delayed hypersensitivity response to penicillins, usually a rash. Occasionally, haemolytic anaemia, leukopenia and interstitial nephritis may occur. There is a 10 percent hypersensitivity crossover with cephalosporins.

Precautions

The prolonged use of antibiotics may result in superinfection with nonsusceptible organisms. There is no evidence that the penicillins, cephalosporins or erythromycin are hazardous in pregnancy but metronidazole should be avoided in high dosages and ciprofloxacin must be avoided in all trimesters of pregnancy. Antibiotics are secreted into breast milk and ciprofloxacin should be avoided in lactation. Other antibiotics, such as the penicillins and

cephalosporins, are secreted into the breast milk but may not be harmful to the infant. Antibiotics, such as the cephalosporins and ciprofloxacin, cleared by the kidneys may require dosage adjustments in patients with renal impairment. Similarly, antibiotics metabolized by the liver, for example erythromycin, may require dosage adjustments or be avoided in patients with liver failure.

Interactions

Before prescribing a specific medication, the reader is advised to check for interactions in, for example, The British National Formulary. Antibiotics may lead to oral contraceptive failure, probably because of diminished enterohepatic circulation. The anticoagulant effect of warfarin is affected by the penicillins, macrolides, metronidazole and quinolones.

Erythromycin interacts with some antihistamines and cisapride, resulting in cardiac arrhythmias. It also increases the plasma level of a number of drugs.

Metronidazole produces a disulfiram-like reaction with alcohol. Acetaldehyde accumulates in the body producing facial flushing, headaches, palpitations, nausea and vomiting.

Indigestion, iron or zinc therapies must not be taken within two hours of ciprofloxacin since absorption of this antibiotic is significantly affected.

Side effects

Most antibiotics may produce diarrhoea, rashes, blood disorders, nausea and vomiting. Ampicillin and amoxycillin have a unique adverse effect, comprising a rash, in up to 90 percent of patients with mononucleosis or chronic lymphocytic leukaemia. Reversible hearing loss has been reported with erythromycin. Angioneurotic oedema and anaphylaxis are, fortunately, relatively rare.

PREPARATIONS USED IN THE MANAGEMENT OF VERTIGO

Betahistine

Betahistine hydrochloride is commonly prescribed in the management of vertigo, usually when associated with Menière's disease or syndrome.

Betahistine is thought to reduce the endolymphatic pressure through improved microvascular circulation in the stria vascularis of the cochlea¹⁵ or by inhibiting activity of the vestibular nuclei.¹⁶

There is insufficient evidence from high quality randomized trials to say whether or not betahistine has any effect on Menière's.¹⁷ It may reduce vertigo, and possibly tinnitus, but does not seem to influence the hearing loss.

Betahistine should be used with caution in patients with asthma, a history of peptic ulcer disease, in

pregnancy and breastfeeding. It is contraindicated in patients with phaeochromocytoma. The side effects include gastrointestinal disturbance, headaches, rashes and pruritis, however, these are uncommon. Betahistine is prescribed initially at 16 mg three times a day, a maintenance dose of 24–48 mg has been recommended.

Dopamine antagonists

Prochlorperazine (Stemetil®) is a dopamine antagonist and acts centrally by blocking the chemoreceptor trigger zone and thereby blocking the vomiting centre. The vomiting centre also has afferent input from the vestibular apparatus. This region has a high concentration of muscarinic receptors and histamine H₁-receptors.

Prochlorperazine belongs to group three of the phenothiazines. This means it has less sedative effects, fewer antimuscarinic effects but more pronounced extrapyramidal side effects when compared to the other phenothiazine groups.

Prochlorperazine is available as tablets, syrup, effervescent sachets, injection, suppositories and as a buccal preparation (Buccastem®). These last two preparations are useful because patients using prochlorperazine often vomit and fail to absorb the orally ingested form. The oral dosage varies from 5 mg three times a day increasing to 30 mg daily.

Antihistamines

The antihistamines are competitive antagonists of histamine at H₁-receptors, and their main action is on the vomiting centre rather than on the chemoreceptor trigger zone. They have weak anticholinergic effects and may occasionally produce a dry mouth and blurred vision. Drowsiness, occasional insomnia and euphoria are side effects which have been reported. These central effects are accentuated with alcohol. Cinnarazine (Stugeron®) and cyclizine (Valoid®) are less sedating than promethazine teoclate (Avomine®). Cinnarazine has been used in the prophylaxis and treatment of Menière's at a dosage of 30 mg three times a day. Cyclizine may be given in the acute attack orally or parentally at a dosage of 50 mg three times a day.

Gentamicin therapy in Menière's disease

Intratympanic gentamicin therapy was described by Beck and Schmidt¹⁸ in 1978 and has been used both in Canada and the UK. Since its introduction, a variety of gentamicin dosage regimens and methods of administration have been developed and remain in clinical practice. These range from injection through the tympanic membrane, through a grommet or via intratympanic or round window catheters.

Other medical treatment for Menière's disease

The use of salt restriction and diuretic therapy (hydrochlorothiazide, acetazolamide and co-triamterzide 50/25 (Dyazide®)) are aimed at reducing the accumulation of endolymph. Although a study with Dyazide showed a reduction in vestibular symptoms, there was no effect on hearing loss or tinnitus. Acetazolamide may initially increase the hydrops and Brookes and Booth¹⁹ concluded that this drug has no place in treating Menière's disease. Steroids and immunological therapy have also been proposed by those who believe that a disorder of the immune system underlies Menière's disease or syndrome.

DRUGS USED IN SUDDEN SENSORINEURAL HEARING LOSS

Corticosteroids

Steroids are commonly used in patients with sudden sensorineural hearing loss (SSNHL), but evidence for their effectiveness is lacking. There are several alternative dosage regimes when a 'short reducing course' of steroids are required. One such consists of enteric-coated prednisolone, 60 mg on the first day, 50 mg on the second day, 40 mg daily for three days, 30 mg daily for three days and a further reduction so that therapy is discontinued after three weeks. The action, side effects, etc. are discussed in Chapter 34, Corticosteroids in otolaryngology.

Acyclovir

Acyclovir (acycloguanosine) is an antiviral agent active against herpesviruses and is prescribed in patients with Ramsay Hunt syndrome (herpes zoster oticus). It acts by inhibiting nucleic acid synthesis. Herpes simplex and varicella zoster contain a thymidine kinase that converts the acyclovir to a monophosphate that is then phosphorylated by the host cell enzymes of acycloguanosine triphosphate that inhibits viral DNA polymerase and viral DNA syntheses. Selectivity for infected cells is achieved since the DNA polymerase of herpesvirus has a much greater affinity for the activated drug than the cellular DNA polymerase.

Acyclovir may be administered orally at a dosage of 800 mg five times a day for five days. If treatment is commenced prior to 72 hours after the onset of the rash, acyclovir may shorten the rash duration and acute symptoms and reduce the incidence of post-herpetic neuralgia.²⁰ Acyclovir should be used with caution in patients with renal impairment or who are pregnant or breastfeeding. Side effects include nausea, vomiting, gastrointestinal disturbances, rash, photosensitivity and, rarely, hepatitis, acute renal failure and neurological

reactions (see British National Formulary²¹ for further details).

SODIUM FLUORIDE TREATMENT IN OTOSCLEROSIS

Sodium fluoride has been used for 35 years in an attempt to slow down or arrest sensorineural hearing loss in patients with stapedial otosclerosis or after stapedectomy. It has also been used in patients with 'pure' cochlear otosclerosis.

Sodium fluoride is an enzyme inhibitor and reduces osteoclastic bone resorption. The clinical benefit of sodium fluoride is controversial. Causse *et al.*²² found that in 'otospongiosis-otosclerosis', sodium fluoride influenced the underlying bony changes in the labyrinth so as to arrest or prevent the onset of hearing loss. In their prospective clinical double-blind, placebo-controlled study of 95 patients, Bretlau *et al.*²³ found that there was a statistically worse deterioration of hearing loss in the placebo group than in the active treated (40 mg sodium fluoride daily) group. Further work by Colletti²⁴ showed benefit in 50 percent of patients five years after a two-year treatment with sodium fluoride (dosages up to 16 mg/day). Deka *et al.*²⁵ suggested the use of Florical at a dosage of two capsules three times a day in active cochlear otospongiosis. Their study showed that variation in absorption occurs with the use of different preparation and also amongst individuals.

The side effects of sodium fluoride need to be considered. In a prospective case-controlled study of ten patients with otosclerosis receiving sodium fluoride 30 mg/day and matched healthy volunteers, Das *et al.*²⁶ found a high incidence (70 percent) of dyspeptic symptoms in those taking sodium fluoride, as well as histological and electron microscopic abnormalities.

KEY POINTS

- Topical ear preparations can be used for a limited period in discharging ears with a perforated tympanic membrane or a grommet *in situ*.
- The use of topical ear preparations containing a steroid only is contraindicated in untreated infections since the immunosuppressive action of the corticosteroid may exacerbate the infection.
- Flucloxacillin is the antibiotic of choice in cellulitis due to *Staphylococcus*. Penicillin V is used in erysipelas due to *Streptococcus*. Ciprofloxacin is the antibiotic of choice in malignant otitis externa.

Best clinical practice

- ✓ Before prescribing, ensure that the patient is not known to be allergic to the medicine or adjuvants (such as the preservatives).
- ✓ Ensure medication does not interact with patient's established medication or medical conditions.
- ✓ Prescribe medicines at the lowest dose for the shortest time that is effective.
- ✓ Review whether medication is still required.

Deficiencies in current knowledge and areas for future research

- There is insufficient evidence to favour any one particular cerumenolytic and a randomized controlled trial may be useful to determine the most clinically and cost-effective preparations for this purpose.
- There is insufficient evidence from high-quality randomized trials to determine whether betahistine, diuretics, steroids and immune therapy have any effect in Menière's disease.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words acute rhinosinusitis, intermittent rhinosinusitis, chronic rhinosinusitis, persistent rhinosinusitis, fungal rhinosinusitis and medical treatment. The chapter has also relied on a review produced by the European Academy of Allergy and Clinical Immunology (EAACI) that was published as a supplement by *Rhinology* in March 2005.

INTRODUCTION

This chapter covers the medical treatment of all forms of rhinosinusitis. The most effective drugs for managing rhinosinusitis are corticosteroids and antibiotics. The majority of this chapter discusses these two major groups of medication. A separate section is devoted to other medicines that are used in the management of rhinosinusitis. Finally, other medical treatments used in rhinology are discussed under Related topics.

Rhinosinusitis is a significant health problem which reduces the quality of life for individuals and places a large financial burden on society. Effective medical treatment is available for allergic rhinosinusitis and infective rhinosinusitis. The evidence for the effectiveness of medical treatment of rhinosinusitis has been reviewed by the European Academy of Allergy and Clinical Immunology (EAACI) and the authors of this chapter have relied on the EAACI review.¹

Rhinosinusitis is an inflammatory process involving the mucosa of the nose and one or more of the sinuses.

Factors that contribute to the inflammation include mucociliary impairment, bacterial infection, allergy, swelling of the mucosa for other reasons and mechanical obstruction. It is recognized that inflammation around the osteomeatal complex is of particular importance in causing rhinosinusitis. Drug therapy in the treatment of rhinosinusitis is aimed at reducing the factors causing inflammation with the additional aim of ensuring adequate ventilation through the osteomeatal complex.

Acute rhinosinusitis is now known as intermittent rhinosinusitis and the term chronic rhinosinusitis has been replaced by persistent rhinosinusitis (PRS).

TREATMENT OF RHINOSINUSITIS WITH CORTICOSTEROIDS

Topically administered glucocorticoids have improved the treatment of rhinosinusitis and asthma. The efficacy of glucocorticoids may partly depend on their ability to reduce the viability and activation of eosinophils and, in

addition, to reduce the secretion of chemotactic cytokines by the nasal mucosa. The biological action of glucocorticoids is mediated through activation of intracellular glucocorticoid receptors that are expressed in many tissues and cells.

Intermittent rhinosinusitis without nasal polyps

There are a number of high-quality studies where intranasal steroids have been used as an additional treatment to antibiotics, but at present there are no studies where topical nasal steroids have been compared to antibiotics as a single treatment for intermittent rhinosinusitis. Studies are now underway but the results have yet to be published. In published studies, where either a placebo or a topical steroid has been added to antibiotic treatment for intermittent rhinosinusitis, the results generally show that the patients who were treated with a topical corticosteroid improved more rapidly than when the antibiotic was combined with placebo. A representative study is that conducted by Meltzer *et al.*² Mometasone furoate 400 µg a day, was given to 200 patients and placebo to 207 patients, all of whom had intermittent rhinosinusitis. All patients were also treated with amoxicillin clavulanate potassium for 21 days. The symptom score, which considered congestion, facial pain, headache and rhinorrhoea, improved significantly in the mometasone group. The effect was most obvious after 16 days treatment and no side effects were seen. [****]

Gehanno *et al.*³ looked at the effectiveness of systemic steroids in the treatment of intermittent rhinosinusitis. Eight milligrams of prednisolone was given three times a day for five days as an adjunct to ten days treatment with amoxicillin clavulanate potassium in patients with intermittent rhinosinusitis. The diagnostic criteria consisted of facial pain, purulent nasal discharge, purulent secretions from the middle meatus, together with opacities on CT scan. The conclusion was that there was no difference in the therapeutic outcome at day 14 between the steroid group and the placebo group, although four days after initiating treatment, the headache and facial pain was significantly less in the steroid group. [****]

Persistent rhinosinusitis without nasal polyps

The majority of studies have compared the effects of topical steroid versus placebo as an adjunctive treatment to antibiotics. Two large trials of 407 and 967 patients, respectively, found that mometasone furoate produced a significant improvement in symptom score over the placebo. In one study,⁴ topical steroid did not help the symptom of post-nasal drip but it did in the second study.⁵ In both these studies there was no statistical

difference in the CT findings of the treatment group compared with placebo.

A recent multicentre double-blind placebo-controlled randomized trial of 134 patients with persistent rhinosinusitis took a different approach in that topical budesonide was compared against placebo after all the patients had received and had not been cured by two weeks of antibiotics. The treatment period was for 20 weeks and the topical steroid produced a significant reduction in nasal congestion and discharge scores and improved the patient's sense of smell when compared with placebo. Peak nasal and inspiratory flows also significantly improved in both allergic and nonallergic patients.⁶ [****]

Persistent rhinosinusitis with nasal polyps: topical steroids

In patients with persistent rhinosinusitis and nasal polyps the studies have tended to consider the effectiveness of the treatment on the rhinitic symptoms and then, as a separate outcome measure, the effect of the treatment on the size of the polyps. In a landmark paper published in 1979, Mygind *et al.*⁷ showed that beclomethasone dipropionate (BDP), at a dose of 400 µg daily for three weeks, reduced nasal symptoms in 19 patients with nasal polyps when compared to a controlled group of 16 patients treated with a placebo aerosol. There was no reduction in the size of the polyps during this short treatment period. [****]

Subsequent studies in which a topical steroid has been compared to placebo in patients with persistent rhinosinusitis and nasal polyposis, have generally shown that the topical steroid is more effective than placebo in reducing the patient's symptoms and, in particular, the symptom of nasal blockage. In approximately half of the reported studies an improvement in the sense of smell occurred and, again, in approximately half the studies the topical steroid also reduced the size of the polyps. The treatment interval in the various studies varied from between 3 and 120 weeks. [****/****]

A comprehensive study compared fluticasone propionate, 400 µg daily, with BDP 400 µg daily and with topical placebo over a 12-week period in a double-blind randomized parallel group that was conducted in a single centre study.⁸ The symptom score was significantly improved in the fluticasone group and the nasal cavity volume improved in both active treatment groups when measured with acoustic rhinometry. The peak nasal and inspiratory flow also improved in both active groups but the improvement was quicker in the FP group. After 12 weeks there was no difference statistically in the symptoms between the two active groups. [****]

In conclusion, therefore, there is good evidence that topical corticosteroids improve the symptoms associated with nasal polyps, in particular nasal blockage, nasal

secretions and sneezing, and in some patients they are effective at improving the sense of smell. In the majority of patients, but not all, topical corticosteroids also appeared to reduce the size of the nasal polyps, provided they were used for several weeks.

Persistent rhinosinusitis with nasal polyps: systemic steroids

There are no studies on treatment with systemic steroids alone in patients with nasal polyps. Topical steroids have always been given as well. Placebo-controlled studies are also lacking but there is a clinical acceptance that systemic steroids have a significant effect on the symptoms of nasal polyposis. [*]

In one study, oral prednisolone was given in doses of 60 mg daily to 25 patients with severe nasal polyposis for four days and, for each of the following 12 days, the dose was reduced by 5 mg daily. Antibiotics and antacids were also given. Seventy-two percent of patients experienced a symptom improvement due to the involution of polyps and in 52 percent of patients an improvement was seen on the CT. The symptoms of nasal obstruction and the sense of smell were improved. The findings of this study support the general clinical impression that systemic steroids are highly effective in treating a patient's symptoms when the patient is actually taking the systemic steroid. Unfortunately, the beneficial effects seem to be lost once the steroid is stopped.⁹ [**]

There have been anecdotal reports of injecting corticosteroid directly into the polyp or into the inferior turbinate. There is no evidence to support this treatment and there have been case reports of blindness following intranasal injection of steroid, and so this method is not to be recommended.

The postoperative treatment of patients with chronic rhinosinusitis and nasal polyps with steroids

To date, there have been six studies into the effectiveness of topical steroids against a placebo and their ability to prevent recurrence of nasal polyps. Topical steroids do reduce the recurrence rate of nasal polyps after nasal polyp surgery. To quote from two of the representative studies, Karlsson and Rundcrantz¹⁰ treated 20 patients with BDP and 20 were followed with no treatment after polyp surgery. The follow-up period was for 30 months. After six months, there was a statistically significant difference between the groups in favour of BDP and its effect increased during the study period over the next 30 months.

Hartwig *et al.*¹¹ used budesonide six months after polypectomy in a double-blind parallel group on 73 patients. In the budesonide group, 'polyp' scores were

significantly lower than in the controls after three and six months. Interestingly, this difference was only significant for patients with recurrent nasal polyposis and not those who had had a polypectomy operation for the first time. [****]

TREATMENT OF RHINOSINUSITIS WITH ANTIBIOTICS

The exact incidence of rhinosinusitis within populations is not known but it is a common condition for which antibiotics are frequently prescribed. According to the National Ambulatory Medical Care Survey in the USA, rhinosinusitis is the fifth most common diagnosis for which antibiotics are prescribed, accounting for 9 and 21 percent of all paediatric and adult antibiotic prescriptions, respectively, written in 2002.¹²

Intermittent (acute) acquired rhinosinusitis

There are more than 2000 studies in the literature concerning the effect of antibiotic treatment on intermittent sinusitis. However, only 49 studies met the appropriate criteria for inclusion in a systematic review in the Cochrane Library. These criteria included placebo control, appropriate statistical analysis and sufficient sample size, together with an adequate description of clinical improvements or success rates.¹³ Amongst these 49 studies, major comparisons were between antibiotic versus control; the newer nonpenicillin antibiotics (macrolides) versus penicillins, and finally the amoxicillin/clavulanate versus other extended spectrum antibiotics. Most trials were conducted within ENT departments and only 20 of the 40 trials were double-blinded. [****/****]

In the studies looking at antibiotic versus control, in general, both penicillin and amoxicillin were more likely to effect a cure than placebo, typical figures being an 82 percent cure for amoxicillin against a 68 percent cure for placebo.¹³

When comparisons were made between the newer nonpenicillins (cephalosporins, macrolides, minocycline) versus penicillins (amoxicillin and penicillin V), no significant differences were shown. The rates of cure or improvement appeared to be 84 percent for both antibiotic classes. Drop-outs due to adverse effects were infrequent and there was no significant difference between the two groups of antibiotics. Sixteen trials involving 4818 patients compared newer nonpenicillin antibiotics (macrolide or cephalosporin) to amoxicillin/clavulanate. Rates for cure or improvement were 72.7 and 72.9 percent for the newer nonpenicillins and amoxicillin/clavulanate, respectively. Drop-out rates due to adverse effects were significantly lower for the cephalosporin

antibiotics. Relapse rates within one month of successful therapy did not differ between the groups.

Six trials, of which three were double-blinded, involving 1067 patients, compared a tetracycline (doxycycline, tetracycline, minocycline) to a heterogeneous group of antibiotics (folate, cephalosporin, macrolide, amoxicillin) and no relevant differences were found.

The Cochrane reviewers¹³ concluded that for intermittent rhinosinusitis, confirmed radiologically, current evidence is limited but supports the use of penicillin or amoxicillin for 14–17 days. [****/***] In the Cochrane review, local differences in susceptibility of microorganisms to antibiotics used were not acknowledged, although it is known that resistance patterns of predominant pathogens, such as *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Moraxella catarrhalis*, vary considerably.¹⁴ The prevalence and degree of antibacterial resistance in common respiratory pathogens is also increasing worldwide, presumably because of the increase in antibiotic consumption. The choice of which antibiotic is used will not be the same in all regions. The selection may depend on local resistance patterns and the disease aetiology.

Antibiotic treatment for persistent rhinosinusitis

It is significantly more difficult to evaluate the efficacy of antibiotic treatment in PRS compared to intermittent rhinosinusitis because of the difficulties of defining the clinical diagnosis of PRS in the literature. In many studies there is no radiological diagnosis and, therefore, data supporting the use of antibiotics in persistent rhinosinusitis is limited and there are no randomized placebo-controlled clinical trials.

In a double-blinded prospective study by Legent *et al.*,¹⁵ 251 adult patients with PRS were treated with ciprofloxacin or amoxicillin/clavulanic acid for nine days. Only 141 of the 251 patients had positive bacterial cultures from the middle meatus at the beginning of the study. At the end of the treatment period, the nasal discharge disappeared in 60 percent of the patients in the ciprofloxacin group and 56 percent of those in the amoxicillin/clavulanic acid group. The clinical cure and bacteriological eradication rates were 59 and 89 percent for ciprofloxacin versus 51 and 91 percent for amoxicillin/clavulanic acid, respectively. The differences were not significant. [***]

There is some evidence that long-term treatment with low-dose macrolide antibiotics may be effective in treating patients with PRS that has not been cured by surgery or corticosteroid treatment. In animal studies, macrolides have been shown to increase mucociliary transport and reduce goblet cell secretion. There is evidence *in vitro*, as well as clinical experience, that macrolides reduce the virulence and tissue damage caused

by chronic bacterial colonization without actually eradicating the bacteria.

Clinical studies have shown that long-term treatment with macrolide antibiotics increases ciliary function.¹⁶ In a prospective randomized controlled trial (RCT), 90 patients with polypoid and nonpolypoid PRS were randomized to oral macrolide (erythromycin) for three months, or endoscopic sinus surgery, and the patients were followed for over a year. The outcome measures included a symptom score, the SNOT 22, the SF 36, nitrous oxide levels, acoustic rhinometry, saccharine clearance times and nasal endoscopy. Both the medical and surgical treatment of PRS significantly improved almost all the subjective and objective parameters with no significant difference between the two groups, or between polypoid and nonpolypoid PRS, except for the increase in total nasal volume which was greater following surgery.¹⁶

To summarize, for persistent rhinosinusitis, there are no placebo-controlled studies on the effectiveness of antibiotic treatment. Studies comparing different antibiotics did not show any significant difference between ciprofloxacin versus amoxicillin/clavulanic acid. The few available prospective studies showed a positive effect on the patient's symptoms in 56–95 percent of patients. [***]

Long-term low-dose macrolide treatment may be of use if surgery and/or steroids have failed. Placebo-controlled studies should be performed to establish the efficacy of macrolides if this treatment is to be accepted in the future. There is also an urgent need for randomized placebo-controlled studies to investigate the effectiveness of antibiotics in general for persistent rhinosinusitis.

TREATMENT OF RHINOSINUSITIS WITH OTHER MEDICINES

Decongestants

After corticosteroids and antibiotics, the medications that are perceived to be most useful for treating rhinosinusitis are decongestants. The rationale behind the use of decongestants is to improve sinus ventilation and drainage. Radiological studies show that topical decongestants markedly reduce the size of the inferior and middle turbinates and improve osteomeatal complex patency.¹⁷

Experimental studies suggest that topical decongestants (xylometazoline and oxymetazoline) have a beneficial antiinflammatory action that is caused by decreasing nitric oxide synthetase.¹⁸ A controlled clinical trial showed that there was improved mucociliary clearance *in vivo* after two weeks of oxymetazoline for persistent bacterial rhinosinusitis when compared to fluticasone and hypertonic saline. The clinical course of the disease between the three groups, however, was not significantly indifferent.¹⁹ [***]

Topical decongestants are also recommended for individuals who have problems clearing their ears while flying or diving. The decongestants are all alpha adrenergic agonists and act on the two types of alpha receptor, one of which controls the venous capacitance vessels of the nasal tissues which are responsible for erectile function, and the other alpha receptors which mediate contraction of arterioles that supply the mucosa. [*]

Ephedrine nasal drops (0.5 and 1 percent) are the weakest of the sympathomimetic preparations, whilst oxymetazoline and xylometazoline are more potent and cause intense vasoconstriction. The rebound effect that occurs after the vasoconstriction wears off is more likely to occur with the potent decongestants and, generally, patients should be advised not to use topical decongestant for more than ten days. In patients who become addicted to decongestant drops or sprays, there is a risk of developing rhinitis medicamentosa and, in this condition, the nasal mucosa becomes permanently damaged.

One preparation combines the steroid dexamethasone isonicotinate with the sympathomimetic tramazoline hydrochloride (Dexa-Rhinaspray Duo). The spray is promoted for the treatment of allergic rhinitis. The suggestion is that the decongestant allows better mucosal access for the steroid. Clinical experience suggests that this is a useful spray. [*] The use of all sympathomimetic preparations is contraindicated in patients on monoamine oxidase inhibitors (MAOIs) and they should be used with caution in patients with hypertension, hyperthyroidism, cardiovascular disease, diabetes mellitus and closed angle glaucoma, and in infants of less than three months of age.

The use of decongestants for persistent rhinosinusitis has not been evaluated in any RCTs. There are no controlled trials to test the efficacy of decongestants for the treatment of nasal polyps.

Systemic decongestants appear to be less effective than local preparations but rebound nasal congestion on withdrawal of the drug does not arise. Pseudo-ephedrine is available over the counter in the UK, both in tablet form and as a linctus. There is little evidence to support the use of systemic decongestants in the treatment of rhinosinusitis.

Mucolytics

The rationale for using mucolytics in the treatment of rhinosinusitis is that they may reduce the viscosity of the nasal secretions. There is minimal evidence to support the use of mucolytics in the treatment of rhinosinusitis. In one paediatric study, an RCT did not prove a bomehine to be superior to saline inhalation for children with PRS.²⁰ [****]

Antihistamines

These can be used both orally and as a nasal spray. Clinical experience suggests that they reduce rhinorrhoea, sneezing and itching, but have little effect on nasal obstruction. There is no evidence that antihistamines reduce or abolish the symptoms of the common cold. The nonsedating antihistamines, acrivastine (Semprex), cetirizine hydrochloride (Zirtek), desloratadine (Neoclarityn), fexofenadine hydrochloride (Telfast) and terfenadine (Triludan) cause less sedation and psychomotor impairment because they penetrate the blood-brain barrier to a lesser degree than the older type of antihistamines. Terfenadine, however, was found to be associated with hazardous arrhythmias. The side effects of antihistamines include hypotension, hypersensitivity reactions, extrapyramidal effect, dizziness, blood disorders and liver dysfunction.

In the treatment of intermittent rhinosinusitis, the beneficial effect of loratadine (the predecessor of desloratadine) for patients with allergic rhinitis was confirmed in a multicentre randomized double-blind placebo-controlled trial. Patients receiving loratadine as an adjunct to antibiotic treatment suffered significantly less sneezing and obstruction on daily visual analogue scale (VAS) scores.²¹ [****]

In PRS, there is little evidence that antihistamines are effective. However, they are often prescribed for patients with PRS, particularly in the USA. There are no controlled trials evaluating such treatment.

Sprays such as azelastine hydrochloride (Rhinolast) and levocabastine (Livostin) are topical antihistamines that are promoted for use in allergic rhinitis. Topical antihistamines are considered less effective than topical steroids and good evidence to support their use is lacking.

Sodium cromoglicate

Sodium cromoglicate is available as a 4 percent aqueous nasal spray (Rynacrom) and a 2 percent nasal spray (Vividrin), and it is also combined with xylometazoline (Rynacrom) and is promoted for prophylactic use in allergic rhinitis. Depending on the preparation, it needs to be taken either four or six times a day. Its mechanism of action is debatable; it was originally thought to act by preventing mediator release from mast cells. However, agents subsequently developed with this property do not demonstrate the same anti-asthmatic effects as cromoglicate. There is some evidence that cromoglicate depresses the exaggerated neuronal reflexes generated by irritant receptor stimulation. The side effects are few and include local irritation and transient bronchospasm. It may have a role in the treatment of allergic rhinitis in children but the fact that it needs to be taken several times a day means that compliance is low. [**]

Antimycotics

There is increased interest in the role of fungi as a possible cause for the various types of rhinosinusitis. Antimycotics can be used topically and systemically and as an adjunct to sinus surgery in the treatment of allergic rhinosinusitis, invasive fungal rhinosinusitis and conventional intermittent rhinosinusitis.

Surgery is considered the first-line treatment for allergic fungal rhinosinusitis,²² and surgery and systemic antimycotics are used in the treatment of invasive fungal rhinosinusitis.²³ Although the use of antimycotics in the treatment of allergic fungal rhinosinusitis has not been tested in controlled trials, a high dose of postoperative itraconazole, combined with oral and topical steroids in a cohort of 139 patients with allergic fungal rhinosinusitis, reduced the need for revision surgery.²⁴ [**] The optimum medical treatment for invasive fungal sinusitis is not known because the available evidence comes from small series and case reports which do not meet the criteria for a meta-analysis. [**/*]

A group of researchers from the Mayo Clinic produced the hypothesis that persistent rhinosinusitis may arise because of a local immune response to fungi that are present in nasal and sinus secretions.²⁵ Given the correct equipment, fungi can be detected in nasal secretions in virtually all patients with PRS, but also in a controlled disease-free population. As yet, there is no definitive proof that fungi are involved in the aetiology of the inflammatory response in some patients. One double-blind randomized placebo-controlled trial has looked at this in 60 patients with PRS, giving them topical treatment with amphotericin B, comparing this with saline douching.²⁶ Radiological and subjective scores were actually worse in the treatment group; however this is an area of considerable interest and further randomized controlled trials are awaited. [***]

MEDICATION THAT MAY IMPROVE THE IMMUNE RESPONSE

It is thought that an altered immune response to bacterial infection or fungal infection may be responsible for some of the episodes of recurrent rhinosinusitis. With resistance to antibiotic treatment increasing, there is interest in medications that may alter the immune response.

Bacterial lysate preparations

Bacterial lysate preparations, e.g. ribosomal fractions of *Klebsiella pneumoniae*, *Streptococcus pneumoniae*, *Streptococcus pyogenes* and *Haemophilus influenzae*, have been tested against placebo in three multicentre placebo-controlled trials and the evidence from these studies

suggested that this type of therapy may reduce the need for antibiotics in the treatment of PRS.^{27, 28, 29} [****]

Treatment with more expensive agents that either stimulate or modulate the immune system, e.g. recombinant human granulocyte colony stimulating factor, have been tested in a randomized controlled trial in a group of patients with PRS that were refractory to other types of treatment. The studies showed there was no significant improvement with this expensive treatment. [****]

A pilot study has looked at treatment with gamma interferon and it suggested that this treatment may be beneficial in treating resistant PRS but the number of patients was small.³⁰ [**]

NASAL AND ANTRAL IRRIGATION WITH SALINE

Saline irrigation

A number of randomized controlled trials have tested nasal irrigation with isotonic or hypertonic saline in the treatment of intermittent and persistent rhinosinusitis. In these randomized trials, modalities of application of the saline or hypertonic saline are compared. The evidence is that nasal washout with isotonic or hypertonic saline is beneficial in alleviating symptoms and improves endoscopic findings in patients with PRS. Irrigation with saline has also shown to significantly improve nasal mucociliary clearance, as measured by saccharine tests in healthy volunteers.³¹ [***]

ANTILEUKOTRIENES

The role of leukotrienes in the pathogenesis of bronchial asthma has been well documented and increased levels of these mediators have been detected in patients with rhinosinusitis and nasal polyps. Antileukotrienes have been evaluated in the treatment of asthmatics, especially in those with the aspirin-induced asthma (ASA) triad.

When seasonal allergic rhinitis was considered, antileukotrienes were not found to be superior to placebo in reducing symptom scores in a randomized controlled trial.³² [****]

For patients with PRS and nasal polyps, one study looked at antileukotriene treatment in 36 patients and found that when antileukotrienes were added to standard treatment regimes, there was a significant reduction in symptom score.³³ [***]

Two other studies support the use of antileukotriene treatment as an adjunct to standard treatment in patients with nasal polyps, asthma and aspirin intolerance.^{34, 35} [**]

Aspirin desensitization

This treatment has been used in patients with nasal polyps. A case-controlled trial of treatment with lysine aspirin to one nostril and placebo to the other in 13 patients with bilateral nasal polyposis, resulted in delayed polyp recurrence on the lysine aspirin-treated side.³⁶ [***] A large randomized controlled trial is underway at the Royal National Throat, Nose and Ear Hospital in London.

AGENTS USED TO BLOCK THE PARASYMPATHETIC NERVOUS SYSTEM

Ipratropium bromide (Rinatec) is a muscarinic receptor antagonist and therefore blocks the parasympathetic nervous system. In theory, it should be effective in anyone with a wet dripping nose due to parasympathetic overactivity. In practice, it is effective for some elderly men with a dripping nose. It does not have any other clinical use and there are side effects which include a dry mouth, epistaxis and dryness of the nose. [*]

RELATED TOPICS

Preparation of the nasal mucosa prior to surgery

Cocaine solution (5 or 10 percent) or cocaine paste (25 percent) has been used to prepare the nose prior to surgery for over 100 years. The majority of rhinologists believe it to be the most effective way of ensuring good operating conditions. As with all local anaesthetic techniques, leaving sufficient time for the drug to work is paramount. The application of Moffat's solution by a spray (**Figure 36.1**) is one method of preparing the nose and it is sensible to do this immediately after the induction of anaesthesia.

Moffat's solution consists of 2 mL of 5 percent cocaine, 1 mL of 1:1000 adrenalin and a small amount of bicarbonate solution. In order to avoid systemic effects, the maximum dose recommended for application to the nasal mucosa in fit adults is 1.5 mg/kg. Colouring the cocaine solution with pink dye reduces the risk of it being mistaken for other drugs in the anaesthetic room.

Antifungal agents used in rhinology

Fungal infections may be superficial or systemic. Antifungal agents can be classified into polyenes, flucytosine, imidazoles and triazoles. The polyenes, amphotericin and

© Hodder Arnold / Scott-Brown 7E

Figure 36.1 The application of Moffat's solution by a spray.

nystatin interact with ergosterol in the fungal cell membrane. Pores are formed through which the fungal cell contents are lost. Selectivity is obtained since the human cell membrane contains mostly cholesterol rather than ergosterol.

Amphotericin has a wide spectrum of activity and is used parentally in severe systemic infections since oral absorption is poor. Side effects are common and include nausea and fevers. Renal impairment can occur but is reversible if detected early. Liposomal amphotericin is significantly less toxic but is more expensive. It is likely that it will become the agent of choice. Nystatin is used principally for *Candida albicans* infections of the skin and mucosal membranes.

Flucytosine is given orally or intravenously to treat systemic candidiasis or cryptococcal infections, often in combination with amphotericin to prevent resistance. Flucytosine is converted in fungal cells to flurouracil which inhibits DNA synthesis.

The imidazoles, miconazole, ketoconazole and clotrimazole, are mostly used to treat topical infections. They are broad-spectrum antifungals that prevent ergosterol synthesis. Ketoconazole is better absorbed by mouth than the other imidazoles but it has been associated with fatal hepatotoxicity.

The triazoles include fluconazole and itraconazole and both can be given orally and parentally. Itraconazole is active against *Aspergillus* but has been associated with hepatotoxicity.

Vestibulitis

Noninfective vestibulitis may be treated by applying vaseline or a mild topical corticosteroid to the vestibule. In the presence of infection, however, an antibiotic ointment should be applied and the infective agent is usually *Staphylococcus aureus*. Two preparations are available in the UK, a combination of chlorhexidine and

neomycin (Naseptin) and mupirocin (Bactroban nasal). The latter is used as a second-line agent for the eradication of methicillin-resistant *Staphylococcus aureus* (MRSA). The ointment is applied three times a day for five days and a swab is taken two days later to determine whether MRSA has been successfully eradicated. Naseptin, when it is used, should be applied four times a day for ten days to treat an infection. It is important to remember that naseptin includes arachis (peanut) oil and this should therefore not be used in patients who have an allergy to peanuts. Naseptin is also contraindicated in pregnancy.

Hereditary familial telangiectasia

The epistaxis associated with hereditary familial telangiectasia (HFT) is difficult to treat and a variety of medical and surgical treatments have been tried. Systemic and topical oestrogen provoke squamous metaplasia of the epithelium and in this way provide a protective coat over the blood vessels. Ethinyloestradiol may be used under supervision for the treatment of HFT in women. The side effects include nausea, fluid retention and thrombosis. It is not popular in men because of the gynaecomastia it induces.

Atrophic rhinitis

Atrophic rhinitis is characterized by a dry crusting mucosa, nasal obstruction and a foul smell. Steam inhalation and humidification are useful, as is nasal douching with saline. A 25 percent glucose in glycerine solution appears to restore some moisture to the nasal mucosa. [*] To prepare the solution, 75 g of glycerine is gently warmed to which 25 g of glucose is added and the mixture stirred until the glucose has dissolved. After bottling, the drops have a three-month life span. The drops can be used several times a day and provide some relief to this distressing condition.

METHODS OF ADMINISTERING TOPICAL NASAL PREPARATIONS

Nasal sprays: If two sprays are to be administered to each nostril, one spray should be directed upwards and the other backwards whilst the patient does not breath or breaths in gently.

The best position for administering nasal drops is head-down as in **Figure 36.2**.

- If betamethasone drops are used it is difficult for the patient to put two drops only into each nostril. In order to establish an exact dose of betnesol drops, they can be decanted into an empty cophenylcaine spray bottle and the patient instructed to put one

© Hodder Arnold / Scott-Brown 7E

Figure 36.2 The best position for administering steroid drops.

spray in each nostril once daily. One spray is equivalent to two drops.

- Topical steroid drops (fluticasone or betamethasone) give a higher systemic dose (approximately equivalent to 2 mg of prednisolone daily) than the topical steroid sprays (triamcinolone acetonide – nasacort at 55 µg per spray, mometasone furoate – nasonex at 50 µg per spray).
- Fluticasone propionate nasules (400 µg) can be used to increase the topical dose of steroid. One nasule is shared between each nostril once daily; thus the dose given is precisely known.

KEY POINTS

- Rhinosinusitis is one of the most common health care problems. It diminishes patients' quality of life and consumes resources.
- Corticosteroids and antibiotics are effective treatments for rhinosinusitis.
- Topical decongestants are a useful adjunct.
- Antihistamines reduce rhinorrhoea, sneezing and itching but not nasal obstruction.
- Antimucolytics are indicated for invasive fungal rhinosinusitis and their role may extend to other types of rhinosinusitis in the future.
- Saline irrigation of the nose is an effective treatment for rhinosinusitis.
- Antileukotrienes, used as an adjunct, work in 50 percent of patients with the ASA triad.
- Topical aspirin desensitization may improve nasal obstruction in PRS with and without polyps. Further trials are underway.
- Topical cocaine remains the best way to prepare the nose for surgery.

Best clinical practice

- ✓ Topical steroids improve the symptoms associated with nasal polyps and reduce the recurrence rate of nasal polyps after surgery.
- ✓ The best position for administering steroid drops is head-down (Figure 36.2).
- ✓ One way of introducing cocaine into the nose is by spraying Moffat's solution (cocaine and adrenalin) into the nose immediately after induction of anaesthesia, increasing the chances of obtaining a 'bloodless surgical field'.
- ✓ Before prescribing naseptin, ensure the patient is not allergic to peanuts.

Deficiencies in current knowledge and areas for future research

- Topical steroids reduce the recurrence rate of nasal polyps following surgery and antileukotrienes help 50 percent of patients with the ASA triad, but there is yet to be an effective long-lasting medical polypectomy.
- The optimum length of treatment with topical steroids is yet to be established with the different clinical scenarios. The role of fungi in the aetiology of rhinosinusitis has yet to be clarified. The current role of systemic and topical antifungal medication may be extended in the future.
- Placebo-controlled trials are required to study the effectiveness of antibiotics for persistent rhinosinusitis. Currently, there is considerable interest in macrolide antibiotics.
- It is not known why some patients with rhinosinusitis develop polyps and others do not.

SEARCH STRATEGY

The data in this chapter are supported by a Medline search using the key words anticoagulant, antibiotic prophylaxis, and head and neck surgery. This chapter relied on the medicines listed in the *British National Formulary*.¹

INTRODUCTION

The laryngologist and head and neck surgeon prescribes medicines for prophylactic purposes, for example antibiotics and anticoagulants, as well as for therapeutic use in the management of infections, immune conditions and voice/throat problems. An appreciation of the pharmacology, preparations available, side effects and contraindications is required for appropriate and safe prescribing. This chapter addresses these matters.

ANTICOAGULANTS

The perioperative management of patients taking anticoagulants may be complex and should be considered on

an individual patient basis, taking into account the increased risk of haemorrhagic complications in that procedure with the risk of thromboembolism if the anticoagulation therapy was stopped. Where necessary, involvement of the haematology/medical teams is advised.

The anticoagulant drugs heparin and warfarin are widely used in the prevention and treatment of venous thrombosis and embolism perioperatively. Anticoagulants should not be used where there is a history of haemorrhagic disorders, peptic ulcer disease, severe hypertension and severe liver disease. **Figure 37.1** illustrates the clotting pathway and the action of heparin and oral anticoagulants.

Heparin is a family of mucopolysaccharides with a molecular weight of 4000–30,000. The molecules are attached to a protein backbone consisting entirely of

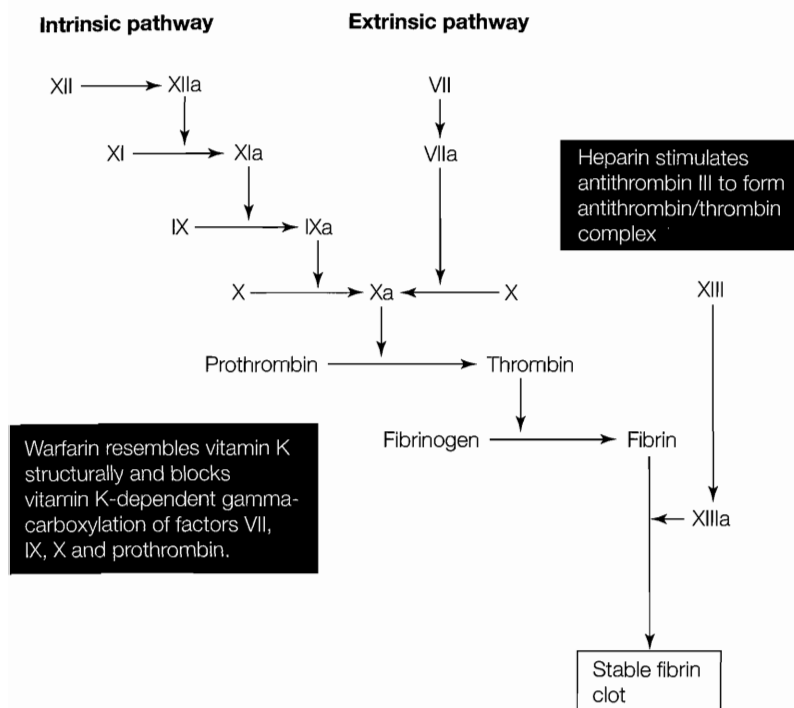

Figure 37.1 The clotting pathway and the mechanism of action of heparin and oral anticoagulants.

serine and glycine residues. Heparin is found in mast cells, in plasma and in the endothelial cell layer of blood vessels. This highly acidic substance is extracted from beef lung or hog intestinal mucosa for therapeutic use. Heparin's main action is preventing fibrin formation by interacting with the protease inhibitor antithrombin III enhancing (by 1000-fold) the binding of antithrombin III with thrombin. In addition, the heparin–antithrombin III complex has inhibitory effects on factors IXa, Xa, XIa and XIIa.

Heparin is not absorbed from the gastrointestinal mucosa because of its charge and large molecular weight; therefore it must be given intravenously or by subcutaneous injection. Intramuscular injection is avoided to prevent haematoma formation. The onset of action of heparin is immediate and it has a half-life of 40–90 minutes. It is inactivated by heparinase in the liver and platelet factor IV released from activated platelets may also have a role.

When used for prophylaxis of deep vein thrombosis in surgery, 5000 units of heparin should be given two hours before surgery, then 8–12 hourly for seven days or until the patient is ambulant. Monitoring is not required in this situation but when used to treat a thrombosis, a regime of 5000 units intravenously followed by 15–25 units/kg/hour intravenous infusion or 15,000 units 12 hourly necessitates monitoring of the thrombin time, which should be increased by a factor of two to three.

Low molecular weight heparins (certoparin, dalteparin, enoxaparin, reviparin and tinzaparin) are also effective in the prophylaxis of venous thromboembolism and their once daily subcutaneous administration is more convenient. These can also be used to treat deep vein thrombosis and monitoring is not required.

Platelet counts should be measured in patients receiving heparin since thrombocytopenia (an immune reaction) may occur but this does not usually happen until six to ten days after the start of treatment. Should thrombocytopenia, or a 50 percent reduction of the platelet count occur, and further anticoagulation is required, patients should be given the heparinoid, danaparoid, or the hirudin, lepirudin.

Heparin inhibits aldosterone and may result in hyperkalaemia, especially in patients with diabetes mellitus, chronic renal failure, acidosis, raised plasma potassium or those taking potassium-sparing drugs.

The oral anticoagulants prevent the reduction of vitamin K that is required as an active cofactor of carboxylase in factors II, VII, IX and X. The effect on fibrin formation depends upon the balance between the decreased rate of carboxylation and the unaltered rate of degradation of factors already carboxylated. Warfarin has a half-life of 40 hours and a duration of action between two and six days. It takes at least 48–72 hours for the anticoagulant effect to develop fully and so heparin is also used initially when an immediate anticoagulant effect is required. Warfarin is the most commonly prescribed oral anticoagulant; nicoumalone and phenindione are rarely used. The drugs are metabolized by the mixed function oxidases in the liver.

Monitoring of the prothrombin time (usually reported as the international normalized ratio (INR) is required and dose adjustments made accordingly. Target INR values (usually between two and four) are detailed in the British National Formulary. The INR can be dramatically altered by co-prescribing other medication and the reader is again directed to the British National Formulary¹ prior to co-prescribing.

ANTIBIOTICS

Antibiotics are commonly prescribed prophylactically, even in so-called clean operations. The use of antibiotics post-tonsillectomy has failed to show a reduction in the secondary haemorrhage rate but may reduce pain at day five postoperatively.^{2,3} Where there is no violation of mucosa, no preoperative inflammation and no drain, the incidence of wound infection in the head and neck is 2 percent. In surgery such as laryngectomy, prophylactic antibiotics with a broad spectrum are used to prevent wound infections. A preoperative dose (given to allow a high tissue level at the time of surgery) and three post-operative doses of a cephalosporin and metronidazole are suitable. Violaris and Bridger, using a cephalosporin at eight hours preoperatively with the premedication and three doses eight hourly postoperatively, reduced the development of pharyngocutaneous fistulae.⁴ Johansen *et al.*⁵ found prophylactic metronidazole resulted in a highly significant decrease in the frequency of post-operative fistulae.

Antibiotic prophylaxis is also necessary in patients with artificial heart valves or cardiac valve disease. Local policies may vary but amoxycillin 3g orally or 1g intramuscularly can be given one hour before surgery and six hours postoperatively.

The choice of antibiotic to treat an established infection is initially on a 'best guess' policy based on the probable pathogen until swab results and sensitivities become available.

PREPARATIONS USED TO IRRIGATE WOUNDS

Before closing a wound following tumour excision it has been recommended that it should first be washed out well. Stell and Maran⁶ describe the use of Savlon, hydrogen peroxide and sterile water as suitable solutions since it appears that the mechanical process of washing rather than the lytic action on the cells is important. They recommend the use of at least 1 L of solution. In a xenograft model of tumour-cell wound contamination, Allegretto *et al.*⁷ found that irrigation with water, saline or gemcitabine delayed tumour development: the latter two improved rates of long-term disease control.

LOCAL ANAESTHETIC SPRAYS AND LOZENGES

These preparations are used to desensitize the mouth and pharynx prior to examination, investigation or treatment. Lidocaine (lignocaine) is effectively absorbed from mucous membranes and is available as a pump spray as a 10 percent solution (maximum dose is 20 sprays in pharynx, larynx or trachea) and more commonly as a topical 4 percent solution (maximum dose is 7.5 mL). Benzocaine is a neutral, water-insoluble local anaesthetic

of low potency and is only used for surface anaesthesia in noninflamed tissue in the mouth and pharynx. It is available in lozenges and sprays, sometimes combined with antiseptics. Sensitization may occur and there is little evidence for the benefit in using these combined preparations. Patients should be advised not to eat or drink until the numbness has worn off. Lidocaine belongs to the amide class, benzocaine to the ester class of local anaesthetics. Both bind to a receptor on the sodium channel in the axon preventing the opening of the channels, thereby preventing depolarization of the nerve. In overdosage, cardiac toxicity can occur.

MOUTHWASHES

Mouthwashes are usually aqueous solutions in a concentrated form of substances with deodorant, antiseptic, local anaesthetic or astringent properties. Sometimes they should be diluted before use. They have a mechanical cleansing action. Hydrogen peroxide mouthwash is a 6 percent solution and 15 mL should be diluted in half a tumblerful of warm water two to three times daily. It contains an oxidizing agent and is useful in the treatment of acute ulcerative gingivitis. It froths in contact with oral debris, thereby having a mechanical cleansing effect, hence its use in the management of secondary tonsillectomy haemorrhages. Chlorhexidine gluconate, used when toothbrushing is not possible or in combating oral infection, inhibits plaque formation on teeth but has the side effect of causing reversible brown staining of the teeth.

THROAT LOZENGES AND PASTILLES

Lozenges and pastilles are both used to deliver medications for local effect, either to soothe or treat infections. Lozenges consist of medicaments incorporated into a flavoured base that dissolves or disintegrates slowly in the mouth. They are prepared either by moulding and cutting or by compression. Colours, flavours and sweetening agents may be incorporated. Heavy compression is used to ensure slow disintegration in the mouth.

Pastilles consist of medicaments in a base containing gelatin and glycerol or a mixture of acacia and sucrose. Sodium benzoate and citric acid monohydrate may be used as a preservative and antioxidant, respectively. Flavourings such as lemon oil may be incorporated.

SOLUTIONS, SUSPENSIONS AND SYRUPS

Solutions are liquid preparations containing one or more soluble ingredients, usually dissolved in water. They may be used internally, externally or for instilling into body cavities and may be sterile or unsterilized depending on

the application. Solutions given orally usually result in rapid absorption. Problems with solubility, taste and stability may prevent this formulation being available for a particular drug.

Suspensions are formulations in which the drug does not dissolve in the solvent but is distributed within it. It usually provides a more rapid dispersion and dissolution of the drug when compared to tablets and capsules so long as the drug has a suitable particle size and does not settle or cake on storage. The primary particle size may grow due to the action of surfactants, emulsifiers and other adjuvants.

Syrups are concentrated aqueous solutions of sucrose or other sugars to which medicaments or flavourings are added. Glycerol, sorbitol and polyhydric alcohols may be added to reduce the rate of crystallization of sucrose and to increase the solubility of other ingredients. Growth of microorganisms is usually retarded by sucrose concentrations greater than 65 percent w/w.

TREATMENT OF DRY MOUTH

Artificial saliva can be useful to relieve dry mouth resulting from radiotherapy or diseases affecting the salivary glands. These preparations should be of neutral pH and contain electrolytes approximating to the composition of saliva. These preparations are available as oral sprays, lozenges and pastilles. Pilocarpine (Salagen) is a muscarinic and can stimulate any residual salivary gland function. Side effects relate to the muscarinic action and its use is contraindicated in those with significant respiratory and cardiovascular disease, angle-closure glaucoma, pregnancy and breastfeeding.

COUGH MEDICINES

These are divided into cough suppressants and the expectorant and demulcent cough preparations. After excluding an underlying cause of a cough, such as asthma and gastro-oesophageal reflux, cough suppressants may be used. It is thought that these drugs act by an ill-defined central action in the nervous system and may depress the 'cough centre' in the brain stem. The narcotic analgesics are effective as antitussives in sub-analgesic doses. Codeine phosphate is useful for dry or painful coughs but it also inhibits the secretion and mucociliary clearance of sputum, is constipating and dependence can develop. Pholcodine (related to codeine) and dextromethorphan (a non-narcotic, nonanalgesic) have lesser side effects. Over the counter preparations include sedating antihistamines, such as diphenhydramine, and may work by causing drowsiness.

There is no evidence that expectorants (ammonium chloride, ipecacuanha and squill) are effective at promoting expulsion of bronchial secretions. Their action is

more placebo. Demulcent cough preparations may relieve a dry irritating cough by virtue of the fact that they contain a syrup or glycerol that has a soothing effect. Simple linctus (a sugar-free preparation is also available) is harmless and inexpensive.

MANAGEMENT OF STRIDOR

The treatment required depends upon the cause and severity of the stridor. Heliox is useful in an acute situation but antibiotics, adrenaline, steroids and antihistamines may be required, as may surgery.

Helium is a colourless, odourless, tasteless gas that when mixed, one volume of helium to two volumes of air, diffuses more rapidly than air itself. Breathing such a mixture requires less effort and an air-helium mixture or a mixture of 21 volumes of oxygen and 79 volumes of helium (Heliox) has been used in the management of stridor.

DRUG THERAPY IN ANGIONEUROTIC OEDEMA

Swelling of the face and lips, and occasionally of the larynx, occurs in angioneurotic oedema of allergic origin. Antihistamines and corticosteroids are prescribed and, if life-threatening, 1 mL/1:1000 adrenaline can be administered subcutaneously. The nonallergic type results from a serum deficiency of the C1 esterase inhibitor protein. An acute attack is treated with an intravenous injection of 36,000 units of C1 esterase inhibitor protein. This can also be given prior to surgery for prophylaxis. Long-term prophylaxis is achieved with epsilon aminocaproic acid or its derivative tranexamic acid or with androgen methyltestosterone or its derivative danazol. These stimulate the production of C1 esterase inhibitor protein.

USE OF BOTULINUM TOXINS IN SPASMODIC DYSTONIA

Botulinum is available as botulinum A toxin-haemagglutinin complex (Botox, Dysport) and botulinum B toxin (NeuroBloc). The dosage is specific to each individual preparation and therefore the product literature must be consulted prior to use. In laryngeal dystonia, localization of the involved muscles and confirmation of correct needle position can be achieved by electromyographic guidance. The effect of botulinum toxin is observed within a few days. Patients may initially have worsening of their voice, dysphagia with the potential for aspiration and occasionally airway compromise. Improvement is seen two weeks post-injections and the effects of treatment may last for three to six months.

Botulinum toxin is contraindicated in patients known to be hypersensitive to ingredients, bleeding disorders,

pregnancy and lactation, concurrent or potential aminoglycoside or spectinomycin administration (neuromuscular blockade is enhanced). It should not be used in patients with generalized muscle disorders such as myasthenia gravis. No information is available on its use in patients with renal or hepatic impairment. Adrenaline should be available in case anaphylaxis occurs.

COLLAGEN INJECTION OF PARALYSED VOCAL CORDS

As a result of Teflon injection being unavailable in the UK, collagen (Contigen) is now used to medialize paralysed vocal cords. It is a purified bovine dermal glutaraldehyde-cross-linked collagen and has been used in genuine stress incontinence. A skin test (0.1 mL collagen and lignocaine, injected intradermally into the volar surface of the forearm) should be carried out four weeks prior to the treatment. Many patients requiring this treatment have a short life expectancy and so a compromise with the skin test performed only a week prior to vocal cord injection is practised. A positive response is defined as erythema, induration, tenderness or swelling with or without purities, persisting for more than six hours or first appearing more than 24 hours after the injection.

The use of collagen injection is contraindicated in patients hypersensitive to the ingredients, with a positive skin test, in pregnancy and lactation and in patients with autoimmune disease or a history of multiple severe allergies.

DRUGS USED IN THYROID DISEASE INCLUDING THE MANAGEMENT OF HYPOCALCAEMIA

Thyroid hormones

The two preparations levothyroxine sodium/thyroxine sodium (Eltroxin) and liothyronine sodium (Tertroxin) are available for use in the management of hypothyroidism, diffuse nontoxic goitre, Hashimoto's thyroiditis and thyroid carcinoma. Levothyroxine sodium (thyroxine sodium) is used for maintenance therapy, usually as a single dose before breakfast. The initial dose is 50–100 µg daily increasing at two to three week intervals by 25–50 µg increments until normal metabolism is obtained. In the elderly, patients with cardiac insufficiency or severe hypothyroidism, the initial dose is 25 µg, increased by 25 µg every four weeks until normal metabolism is achieved. The usual maintenance dose is 100–200 µg, the higher dose is used to suppress T4 in thyroid carcinoma.

Liothyronine has a shorter half-life with a more rapid onset of action and shorter duration of action. Twenty micrograms of liothyronine is equivalent to 100 µg of thyroxine sodium. It can also be given intravenously. A

pretherapy ECG should be performed since hypothyroidism can produce changes resembling ischaemia. The starting dose is 10–20 µg every eight hours. The usual maintenance dose is 60 µg daily in three divided doses. Sometimes it is co-administered with carbimazole to treat thyrotoxicosis. It may be used in severe hypothyroid states when a rapid response is required and is used in patients awaiting radioactive iodine scan following thyroid surgery. The latter enables patients to remain euthyroid in this interval period and patients need to stop liothyronine only two days prior to the scan.

These thyroid hormones must be used with caution in patients with hypertension, diabetes mellitus and insipidus, cardiovascular disorders, angina, the elderly, lactation, pregnancy (especially the first trimester) and in adrenal insufficiency. Interactions include sucralfate, phenylbutazone, warfarin, carbamazepine, phenytoin, rifampicin, barbiturates and propranolol. The side effects of arrhythmias, insomnia, tremor, palpitations, sweating, weight loss, thyroid crisis, vomiting, diarrhoea and headache have been reported.

Drugs used in hyperthyroidism

Antithyroid drugs are used for hyperthyroidism either preoperatively or for long-term management. Carbimazole (Neo-Mercazole) is the most commonly used in the UK; propyluracil is used in patients sensitive to carbimazole. Both are thionamides containing a thiocarbamide group ($S=C-N$) that is essential for their activity. Carbimazole is rapidly converted to methimazole *in vivo*. Methimazole is available in the USA. Thioamides prevent the synthesis of thyroid hormones by competitive inhibition of I^- to I^2 by peroxidase and also block the coupling of the iodotyrosine, especially in forming diiodothyronine. More controversial is the possibility that the thionamides have immunosuppressive properties. These drugs are administered orally and accumulate within the thyroid gland. Their delayed onset of action of three to four weeks results from the need of preformed hormones to be depleted first.

The main concern with thionamides is the development of neutropenia and agranulocytosis. Carbimazole has an incidence of causing agranulocytosis in 0.1 percent of patients; propylthiouracil has an incidence of four times this (explaining the preference for carbimazole in the UK).

The Committee on Safety of Medicines recommends that:

- patients should be asked to report symptoms and signs suggestive of infection, especially sore throat;
- a white blood count should be performed if there is any clinical evidence of infection;
- the drug should be stopped promptly if there is clinical or laboratory evidence of neutropenia.

Iodine is used as an adjunct to antithyroid drugs in the preoperative management of thyrotoxicosis. An aqueous iodine oral solution (Lugol's solution) is given at a dose of 0.1–0.3 mL three times a day, taken well diluted with water or milk. Patients may develop flu-like symptoms, headache, rashes, insomnia, lacrimation, conjunctivitis, laryngitis and bronchitis. It must be used with caution in pregnancy and be avoided in lactation.

Drugs used in hypocalcaemia

Following thyroid or parathyroid surgery, patients may develop hypoparathyroidism either temporarily or permanently. Parathormone is the most important regulator of the extracellular calcium concentration. Hypocalcaemic tetany is initially managed by an initial intravenous injection of 10 mL 10 percent calcium gluconate followed by a continuous infusion of 40 mL daily or oral calcium with careful monitoring of the plasma calcium concentration. Bradycardia, arrhythmias and irritation after intravenous injection may occur as can gastrointestinal disturbances after oral administration. Failure to obtain and maintain a corrected calcium concentration within the normal range with calcium supplements alone necessitates the additional administration of a vitamin D preparation. **Figure 37.2** demonstrates the control of calcium plasma concentration by vitamin D. Vitamin D is a prohormone, metabolized to hormones that increase

intestinal absorption of calcium, mobilize calcium from bone and inhibit renal excretion. The hypocalcaemia of hypoparathyroidism often requires doses of up to 2.5 mg (1,000,000 units) calciferol daily. Calcifediol is the main derivative of liver hydroxylation and this is further hydroxylated in the kidney to the potent calcitriol. The latter step is regulated by parathyroid hormone. A synthetic derivative of vitamin D commonly prescribed in hypoparathyroidism is alfacalcidol.

TREATMENT OF REFLUX OESOPHAGITIS

Initial treatment depends on the severity of the symptoms and treatment response. Antacids and alginates alone may be used for mild symptoms. The alginates are said to form a raft on the surface of the stomach's contents to reduce reflux and protect the oesophageal mucosa.

Histamine H₂ receptor antagonists (cimetidine, famotidine, nizatidine and ranitidine) block the action of histamine on the parietal cells and reduce acid secretion. They should be used with caution in patients with liver or renal disease, in pregnancy and breastfeeding. Side effects include diarrhoea, altered liver function tests, rashes and, more rarely, hypersensitivity reactions, A V block and blood dyscrasias. Cimetidine has been reported to cause gynaecomastia and it binds to cytochrome P-450 reducing the hepatic metabolism of drugs such as warfarin.

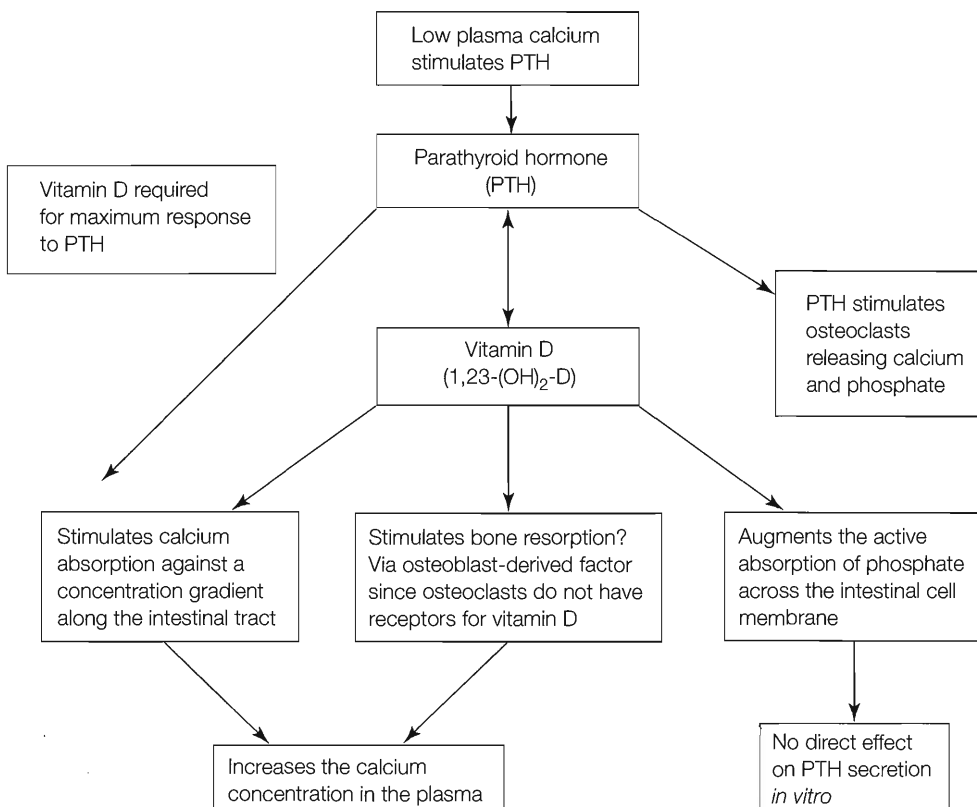

Figure 37.2 Calcium homeostasis and the role of Vitamin D.

The proton pump inhibitors (omeprazole, esomeprazole, lansoprazole, pantoprazole and rabeprazole sodium) react with sulphhydryl groups in the H^+/K^+ ATPase (proton pump) responsible for the transportation of H^+ ions out of the parietal cells.

CHEMOTHERAPEUTIC AGENTS

These drugs are used either alone or in combination with surgery and/or radiotherapy with the aim to cure or palliate a cancer. They inhibit the mechanisms of cell proliferation and rely upon malignant tumours having a greater proportion of cells undergoing division than in normal proliferating cells, especially in the bone marrow, gastrointestinal mucosa and in hair follicles.

Chemotherapeutic agents are classified with respect to their site of action, as demonstrated in **Figure 37.3**.

Alkylating agents (mustine, cyclophosphamide, chlorambucil, cisplatin and busulphan) cross-link the two strands of the double helix of DNA. The antibiotics actinomycin D, doxorubicin, mitomycin, mithramycin and bleomycin interact with the DNA preventing RNA production. DNA synthesis is prevented by a group of antimetabolites (methotrexate, fluorouracil, mercaptopurine and thioguanine) that prevent purine or pyrimidine synthesis. The vinca alkaloids (vincristine and vinblastine) bind to the microtubular proteins inhibiting mitosis. Glucocorticoids are included in regimes since they inhibit cell division by interfering with DNA synthesis.

Side effects such as nausea and vomiting, intestinal ulceration, diarrhoea, alopecia and bone marrow suppression are common but may become life-threatening.

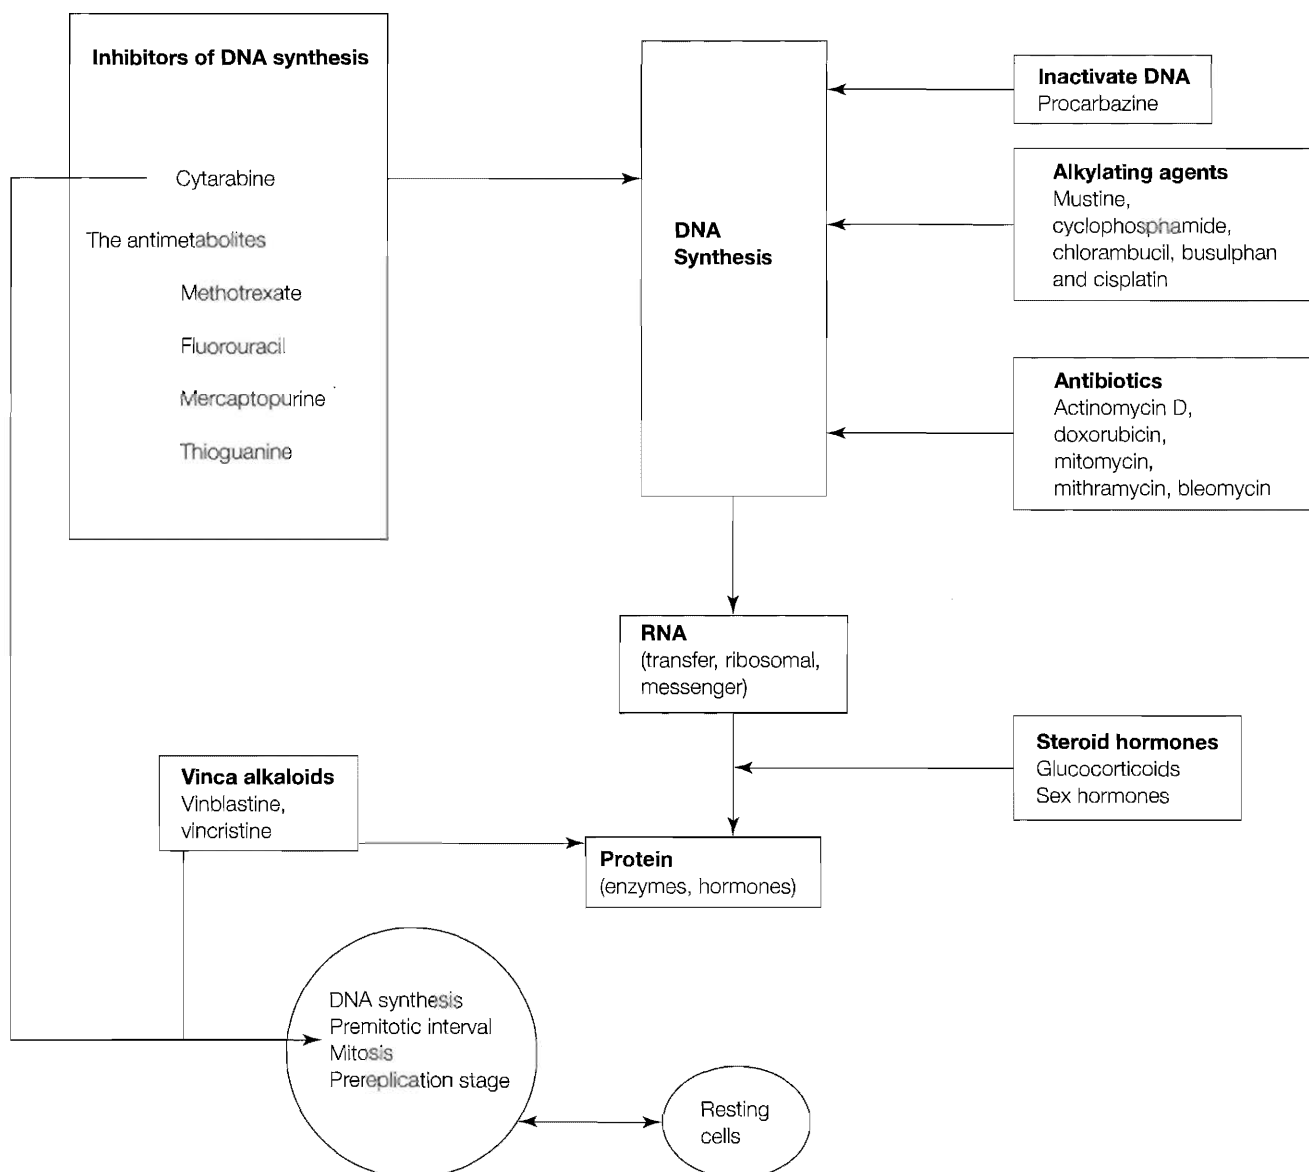

Figure 37.3 Site of action of chemotherapy.

MANAGEMENT OF FUNGATING WOUNDS

Charcoal dressings have been used to help combat malodorous fungating tumours. When this fails, topical metronidazole gel (Anabact or Metrotop) can be applied to the cleaned wound once or twice a day and covered with a nonadherent dressing. The metronidazole has antimicrobial activity against the anaerobes likely to be responsible for the odour.

Alginate dressings may stop bleeding from fungating wounds and, if moistened prior to a dressing change, the risk of bleeding at this time can be reduced.

KEY POINTS

- Perioperative antibiotics have not been shown to reduce bleeding rates after tonsillectomy but may reduce pain.
- The use of perioperative cephalosporins and metronidazole reduce the rates of fistula formation in head and neck operations.
- Pilocarpine (used in the treatment of dry mouth) is contraindicated in patients with significant respiratory/cardiovascular disease, glaucoma, pregnancy or breastfeeding.
- Rarely, carbimazole can cause agranulocytosis.
- Botulinum is available as botulinum A toxin–haemagglutinin complex and botulinum B toxin. It is important to realize that the dosage is specific to each preparation.

Best clinical practice

- ✓ The starting or stopping of anticoagulants should be in accordance with guidance from the haematologist and medical colleagues, taking into account other prescribed medications which may interact.
- ✓ Platelet counts should be monitored in patients on heparin to detect any thrombocytopenia.
- ✓ Cefuroxime and metronidazole should be given at induction and for at least three postoperative doses in head and neck procedures where the mucosa is breached.
- ✓ Heliox is easier to breathe than air and buys useful time in patients with stridor, however, it is important to take additional steps to treat the underlying cause and to secure the airway.
- ✓ First-line treatment of angioneurotic oedema consists of intravenous antihistamines and steroids with nebulized or subcutaneous adrenaline.

- ✓ In order to avoid severe hypersensitivity reactions, preoperative test injections of collagen are necessary where this is used to perform vocal cord medialization.

SEARCH STRATEGY

This included recent publications in scientific journals, from professional bodies and the UK Department of Health, using key words such as consent, suitability for day surgery, preoperative assessment, preoperative preparation and venous thromboembolism prevention.

PATIENT PATHWAY

The patient pathway describes the 'route' taken by a patient from initial referral to regaining health. A pathway includes processes and documentation, and should be amenable to audit and external review. Generally, the surgeon makes a broad judgement at the time of seeing the patient as to whether or not the patient is fit for surgery. The in-hospital segment of the pathway begins here and, within the confines of a busy clinic, the patient requiring surgery should be placed into one of five routes:

1. day surgery;
2. inpatient, scheduled admission within a few weeks;
3. inpatient, elective surgery, fit patient;
4. planned inpatient but requiring prior medical/anaesthetic review;
5. immediate admission.

Suitability for day or ambulatory surgery

It is helpful to be able to refer to guidelines about which patients are suitable for day surgery in a particular

hospital. The National Health Service Modernisation Agency published its recommendations¹ and advice on day surgery in December 2002. Traditional criteria for suitability are outlined in **Table 38.1**.

Table 38.1 Factors indicating suitability for day surgery.

Factors indicating suitability	
Patient	Access to a telephone Responsible adult available for the first 24 hours GP back-up Travelling distance home/day unit < 1 hour Escort to collect Suitable home circumstances
Surgical	Peripheral surgery Duration of surgery < 2 hours Limited blood loss No wound drain Early resumption of oral intake fluid/food
Anaesthetic	No previous or predicted serious anaesthetic problems Post-operative pain control with oral agents only

There are a number of conditions which either exclude day surgery or require considerable thought:

- body mass index (BMI, mass kg/height m²) > 35–40;
- diastolic blood pressure BP > 100 mmHg, systolic > 170 mmHg;
- moderate/severe cardiorespiratory disease;
- patients on haemodialysis;
- advanced liver disease;
- some neuromuscular disorders such as myasthenia;
- opioid dependency if pain relief likely to be difficult;
- limited mouth opening or difficult intubation.

The head and neck surgical procedures recommended in the original Audit Commission basket of day surgery procedures 1990 were myringotomy with or without grommets, submucous resection, reduction of nasal fractures and operation for bat ears. A revised list was proposed by the British Association of Day Surgery (BADS)² in 1999 which added tonsillectomy in children. BADS also suggested a number of procedures of which it felt that 50 percent should be possible as day cases – submandibular gland excision, partial thyroidectomy, superficial parotidectomy, rhinoplasty, tympanoplasty and dentoalveolar surgery. In 2000, the Audit Commission prepared a list or basket of 25 operations suitable for day surgery which included myringotomy, tonsillectomy, submucous resection, reduction of nasal fractures and correction of bat ears. The Healthcare Commission’s latest acute hospital portfolio review³ on day surgery was published in July 2005.

Failure of the initial broad screening will direct the patient into the wrong pathway and may lead to substantial delays or frustration and patient harm. It is the pathway of medical/anaesthetic review prior to surgery that is particularly testing since it involves initial detection of problem patients, sending them for review, initiating treatment as required and waiting for optimal response before admission for surgery. It is clear that perioperative mortality is reduced by preoperative optimization, particularly of cardiac and respiratory disease.⁴

PREOPERATIVE ASSESSMENT

The general health of the patient is assessed to determine whether it can be improved, whether the risk of surgery is worthwhile and to determine the site of perioperative care and the assessment includes:

- problems with previous surgery;
- personal or family problems with anaesthesia;
- cardiovascular system, usual BP;
- respiratory system;
- other diseases;
- bleeding/clotting tendencies;
- assessment of difficulty with airway management;

- presence of significant gastro-oesophageal reflux;
- problems with venous thromboembolism;
- likelihood of postoperative nausea/vomiting (PONV);
- difficulties with pain control;
- medications, allergy, weight;
- smoking, alcohol and recreational drugs;
- current or prior drug dependency;
- home/family circumstances.

A structured form covers the relevant areas, improves data capture,⁵ aids assessment and can be used by nurse specialists.

Problems detected at preadmission clinics are quite varied and need to be resolved before admission. Monoamine oxidase inhibitors present opportunities for serious drug reactions and some anaesthetists feel they should be changed, if possible, to other classes of antidepressants. Special needs patients may require intricate arrangements to attend for surgery on a particular date.

Previous problems with anaesthesia/surgery

Notable problems are a history of latex allergy, anaphylaxis to an anaesthetic agent, artificial colloid or antibiotic, difficult or failed intubation, pulmonary aspiration, post-operative nausea or vomiting, awareness, prolonged action of suxamethonium due to plasma cholinesterase deficiency, malignant hyperpyrexia or unexpected admission to a high dependency or intensive care unit. Elective surgery should be postponed until the nature of the previous incident has been fully understood.

Cardiovascular disease

Relevant conditions are systemic hypertension, valvular disease, arrhythmias, angina (Table 38.2), myocardial infarction, ventricular failure, dyspnoea (Table 38.3), cerebro- or renovascular disease and presence of an

Table 38.2 New York Heart Association (NYHA) classification of angina.

Classification	
0	No angina
1	No limitation of ordinary physical activity. Angina caused by strenuous or rapid, prolonged exertion
2	Slight limitation of normal activity, e.g. angina with rapid walking, climbing stairs, emotional stress
3	Marked limitation of normal activity, e.g. angina on one flight of stairs, but comfortable at rest
4	Incapacitation with angina on mildest effort or at rest

Table 38.3 Dyspnoea grading.

Grade	
0	No dyspnoea whilst walking on level at normal pace
1	Mild, restricted by speed of walking, not distance (OK if I take my time...)
2	Moderate, specific outdoor limitation (Stop after a certain distance...)
3	Marked dyspnoea on mild indoor exertion
4	Dyspnoea at rest

implanted pacemaker or defibrillator. The recent recommendations⁶ of the American College of Cardiology/American Heart Association (ACC/AHA) for perioperative cardiovascular evaluation give the following advice.

- Hypertension with systolic blood pressure greater than or equal to 180 mmHg and diastolic greater than or equal to 110 mmHg should be controlled before surgery. Usually, an effective regimen can be achieved within several days to weeks. With urgent surgery, agents can be administered that allow effective control within hours. Beta blockers are particularly attractive agents.
- Valvular disease. Symptomatic stenotic lesions are associated with high risk and consideration should be given to valvotomy or valve replacement prior to elective surgery. Mild regurgitant valve disease appears to be tolerated well but optimal medical therapy and monitoring should be employed.
- The presence of arrhythmias or cardiac conduction defects should provoke a careful evaluation for underlying cardiopulmonary disease, but the indications for antiarrhythmic therapy or pacing are identical to those in the nonoperative setting. Frequent ventricular extrasystoles are not associated with an increased risk of nonfatal myocardial infarction (MI) or cardiac death.
- Pacemakers should be checked for correct functioning, preferably by a pacemaker clinic, and implantable defibrillators should be turned off immediately before surgery and on again postoperatively.

Risk indices⁷ have been developed over the years and, generally, coronary artery disease, heart failure, cerebrovascular disease, elevated creatinine, insulin-dependent diabetes and high-risk surgery have all been associated with increased perioperative cardiac morbidity. Age is another risk factor⁸ with the overall 30-day mortality associated with surgery and anaesthesia rising from 2.2 percent (age 60–69) to 8.4 percent (age >90 years). The ACC/AHA recommendations place risk factors into three categories of predictors (**Table 38.4**) and provide three levels of surgery-specific risk with head and neck surgery in the intermediate group.

Areas of particular concern are the evaluation of the degree of myocardial ischaemia and function.⁹

Table 38.4 Clinical predictors of increased perioperative cardiac risk.

Severity	Clinical predictor
Major	
Unstable coronary syndromes	Acute or recent MI (<4 weeks) Unstable or severe angina
Decompensated heart failure	
Significant arrhythmias	High grade AV block Symptomatic ventricular with underlying heart disease Supraventricular with fast ventricular rate
Severe valvular disease	
Intermediate	
Mild angina	
Previous MI by history or Q waves	
Compensated or prior heart failure	
Diabetes mellitus (particularly insulin dependent)	
Renal insufficiency	
Minor	
Advanced age	
Abnormal ECG	
Rhythm other than sinus	
Low functional capacity (unable to climb one flight of stairs)	
History of stroke	
Uncontrolled systemic hypertension	

Assessment of coronary artery disease generally involves history, an exercise ECG, followed where necessary by coronary angiography. Angiography may indicate coronary stenosis amenable to stenting or severe disease requiring coronary grafting. Medical treatment of angina is usually with aspirin or clopidogrel, nitrates, beta blockers, calcium channel antagonists or angiotensin-converting enzyme (ACE) inhibitors. Whilst patients with mild, infrequent, stable angina and normal exercise tolerance do not require any additional investigation, it is generally useful to seek cardiological opinion preoperatively for:

- patients with new onset angina who are not on treatment or under review;
- patients with increasing frequency of angina;
- patients with NYHA class 3 or 4 angina.

Heart failure is a serious condition and generally should be evaluated in all patients before surgery. Relevant history is of limited exercise tolerance, dyspnoea,

orthopnoea, paroxysmal nocturnal dyspnoea and ankle oedema. Medical therapy involves frusemide, spironolactone, ACE inhibitors and good control of hypertension or arrhythmias. The best investigation is echocardiography which will demonstrate size of chambers, wall thickness, wall motion, valve function and allow an estimate of ejection fraction. Ejection fraction refers to the proportion of left ventricular blood volume ejected during ventricular contraction. The normal value is 60–65 percent and values below 35–40 percent are significantly reduced and require a raised level of perioperative cardiovascular monitoring. Other investigations look at myocardial perfusion during stress; poorly perfused areas during stress may return to normal on resting (indicating ischaemia) or remain poorly perfused (infarction).

Patients with valvular disease, prosthetic valves or cardiomyopathy are at risk of bacterial endocarditis and should receive antibiotic prophylaxis. The current recommendation for most head and neck surgery under general anaesthesia is for amoxycillin 1 g and gentamicin 120 mg intravenously at induction.

Patients with mechanical prosthetic valves, or with some cardiomyopathies or atrial fibrillation, may be anticoagulated with warfarin. These patients require admission three to four days before surgery so that warfarin may be discontinued and anticoagulation continued with a heparin infusion at an initial rate of 1000 IU/hour adjusted according to the activated partial thromboplastin time (APTT). Aspirin therapy affects platelet function irreversibly and is a contraindication to surgery if small degrees of platelet dysfunction are unacceptable (e.g. neurosurgery). The drug should be stopped, if required, for one month prior to surgery.

Respiratory disease

Common conditions are chronic bronchitis, emphysema, chronic obstructive airway disease and asthma. Generally, a patient with known, mild, stable disease under review by the GP or respiratory department will not need special preoperative assessment. Medical therapy involves inhaled or oral bronchodilators, inhaled or oral steroids, inhaled anticholinergic agents and inhaled agents influencing local immune function. The disease severity can be gauged by history of exercise capability, number of attacks, requirement for admission to hospital or ITU, need for ventilation, requirement for home support or domiciliary oxygen, chest x-ray and respiratory function testing. Asthmatic patients often know their normal peak flow measurement and this is a simple test to carry out. A respiratory physician and anaesthetic review should be sought for patients with respiratory disease who:

- have limited exercise capability;
- have required hospital admission, particularly ventilation;

- are nearly housebound by respiratory symptoms;
- have deteriorating symptoms or signs;
- require home oxygen therapy.

All patients should be advised to stop smoking.

PREOPERATIVE TESTS

Recommendations come from the American Society of Anesthesiologists (ASA) Task Force¹⁰ on preanesthesia evaluation and the Association of Anaesthetists of Great Britain and Ireland.¹¹ Preoperative tests may be routine (a test ordered in the absence of specific clinical indication or purpose) or indicated (ordered for a specific clinical indication or purpose). A consensus view has been reached that preoperative tests may be ordered on a selective basis for purposes of guiding or optimizing perioperative management, but should not be ordered routinely. The Association of Anaesthetists of Great Britain and Ireland states that 'Blanket routine preoperative investigations are inefficient, expensive and unnecessary'.

Written guidelines are, therefore, hospital or department-based and should be discussed during induction of new department members. All patients should undergo 'dipstick' urinalysis for blood, glucose and protein, and pregnancy testing should be offered to relevant patients. Audiometry should be undertaken on all patients undergoing surgery on the middle ear, and vocal cord function visualized when surgery might damage the recurrent laryngeal nerve. Reasonable guidelines for preoperative tests in adult patients undergoing head and neck surgery are:

- haemoglobin in all females, males aged over 40 years and in any patient in whom blood grouping will be undertaken;
- urea and electrolytes in all patients over 40 years or when indicated by disease process or medication;
- clotting studies when indicated by history;
- sickle cell testing in all patients of African or Afro-Caribbean origin;
- pregnancy testing when pregnancy is possible;
- blood grouping (group and save) in patients with a normal preoperative haemoglobin and an anticipated blood loss of 10–15 percent blood volume (blood volume 70 mL/kg in adult), and all patients who have had a previous blood transfusion in case of the presence of antibodies;
- blood grouping and cross-matching in all patients with an expected blood loss in excess of 15 percent blood volume (>750 mL in the average adult) or at significant risk of sudden severe haemorrhage. The number of blood units requested for a particular surgical procedure should follow written guidelines drawn up in consultation with the Hospital Transfusion Committee;

- electrocardiography in any patient with cardiovascular disease or in asymptomatic patients aged over 60–70 years;
- chest x-ray in patients with signs or symptoms of cardiac, respiratory or multisystem disease referable to the chest.

National Institute for Clinical Excellence guidelines on preoperative tests

The National Institute for Clinical Excellence (NICE)¹² produced its recommendations for the use of routine preoperative tests for elective surgery in June 2003. These are guidelines arising from expert opinion using a consensus development process and the clinical experience of the guideline development group. Specific recommendations are made according to:

- grade of surgery 1–4 (minor, intermediate, major, major+);
- ASA status 1–3 (Table 38.5);
- cardiovascular, respiratory or renal comorbidity;
- age of patient.

Table 38.5 Physical status grading of American Society of Anesthesiologists.

Grade	Physical status
Grade 1	Normal healthy patient without any clinically important co-morbidity
Grade 2	Patient with a mild systemic disease
Grade 3	Patient with one (or more) severe systemic disease which does not present a constant threat to life
Grade 4	Patient with systemic disease processes which present a constant threat to life
Grade 5	Patient not expected to survive more than 24 hours

Table 38.6 Tests recommended by NICE for intermediate surgery in ASA 2 patient with cardiovascular co-morbidity.

Test	Age (years)			
	≥ 16 to <40	≥ 40 to <60	≥ 60 to <80	≥ 80
Chest x-ray	?	?	?	?
ECG	Yes	Yes	Yes	Yes
Full blood count	?	?	?	?
Haemostasis	No	No	No	No
Renal function	?	?	Yes	Yes
Random glucose	No	No	No	No
Urine analysis	?	?	?	?
Blood gases	No	No	No	No
Lung function	No	No	No	No

?, local decision required.

Recommendations are made for chest x-ray, ECG, full blood count, haemostasis, renal function, random glucose, urine analysis, blood gases, lung function, sickle cell and pregnancy testing. A wall-chart or booklet shows individual recommendations as green (test recommended), red (test not recommended) and yellow (consider this test). Table 38.6 refers to a patient undergoing intermediate or grade 2 surgery (e.g. tonsillectomy) who is ASA 2 with co-morbidity from cardiovascular disease (perhaps well-controlled, mild hypertension). Table 38.7 refers to a patient undergoing major or grade 3 surgery (e.g. thyroidectomy) who is classed as ASA 3 with co-morbidity from cardiovascular disease. Unfortunately, many recommendations are 'yellow' and individual hospitals or departments are still required to produce their own guidelines. Without these, unnecessary tests will continue to be ordered 'just in case' they are required by the anaesthetist or surgeon. Staff undertaking clinical preoperative assessments should discuss with patients which tests are recommended, what they involve and the possible implications of an abnormal result. Doctors or nurses ordering the tests should write in the notes that they have discussed the recommended tests and their implications with the patient, who should be informed of the results of the tests.

EXPLANATION OF, AND WRITTEN CONSENT FOR, PLANNED SURGERY

Valid consent to treatment is central in all forms of health care, from providing personal care to undertaking major surgery. In the UK, in accordance with the NHS Plan, the Department of Health instituted substantial changes in consent in 2001. The seminal document is 'Good practice in consent implementation guide' available on www.doh.gov.uk/consent.

Consent is a patient's agreement for a health professional to provide care. Seeking consent indicates the

Table 38.7 Tests recommended by NICE for major surgery in ASA 3 patient with cardiovascular co-morbidity.

Test	Age (years)			
	≥ 16 to <40	≥ 40 to <60	≥ 60 to <80	≥ 80
Chest x-ray	?	?	?	?
ECG	Yes	Yes	Yes	Yes
Full blood count	Yes	Yes	Yes	Yes
Haemostasis	?	?	?	?
Renal function	Yes	Yes	Yes	Yes
Random glucose	No	No	No	No
Urine analysis	?	?	?	?
Blood gases	?	?	?	?
Lung function	No	No	No	No

?, local decision required.

whole process of information provision, discussion and decision-making. When a patient formally gives their consent to a particular intervention, this is only the end point of the consent process.

Patients may indicate consent nonverbally (for example by presenting their ear for examination in out-patients), orally or in writing. For the consent to be valid, the patient must:

- be competent to take the particular decision;
- have received sufficient information to take it;
- not be acting under duress.

When an adult patient lacks the mental capacity (either temporarily or permanently) to give or withhold consent for themselves, no one else can give consent on their behalf.

It is good practice to gain written consent if:

- the treatment or procedure is complex or involves significant risks;
- the procedure involves general/regional anaesthesia or sedation;
- providing clinical care is not the primary purpose of the procedure;
- there may be significant consequences for the patient’s employment, social or personal life;
- the treatment is part of an approved project or programme of research.

In the UK, standard forms are used in all NHS hospitals. Four differing forms are available to cover:

1. adult patients undergoing surgery who are competent to consent;
2. parental agreement for a child or young person;
3. adult patients undergoing treatment or procedures where the patient is expected to remain alert and an anaesthetist is not involved
4. when an adult patient is unable to consent.

For an adult patient, the consent process begins with the provision of information to the patient and discussion of treatment options and oral agreement may be reached that particular surgery is appropriate. When written consent is appropriate, the patient should be familiar with the contents of their consent form before they arrive for the procedure and should have received a copy of the page documenting the decision-making process. They may be invited to sign the form at any appropriate time before the procedure – in outpatients, preadmission clinic or when they arrive for treatment. A member of the health care team must check immediately before treatment that the patient has no concerns and that their condition has not changed. Patients must not be under duress to give valid consent and patients should not be expected to give consent when already changed for theatre or, indeed, in the anaesthetic room.

EXPLANATION OF, AND CONSENT FOR, ANAESTHESIA

It is the duty of the anaesthetist to gain consent for anaesthesia, but specific written consent for anaesthesia is not required in the UK. Each patient should receive a general leaflet about anaesthesia in outpatients. This allows the patient time to consider the issues surrounding provision of anaesthesia. Discussion between the anaesthetist and patient addresses (as relevant):

- previous anaesthetic problems;
- likely difficulties or risks in provision of anaesthesia for the planned surgery;
- local versus general anaesthesia;
- general conduct of general anaesthesia and recovery;
- intravenous fluids;
- blood transfusion;
- pain relief;
- control of nausea/vomiting;

- urinary catheterization;
- nasogastric tube insertion;
- placement of arterial and central venous lines.

Patient anxieties are generally to do with death, brain damage, awareness, loss of control, memory loss, pain control, nausea or vomiting and needle insertion.¹³ Premedication with either an anxiolytic or analgesic is discussed and written as required. In the UK it is possible that the preoperative anaesthetic visit will occur only minutes before planned surgery but a better arrangement exists in France. Here, all patients must be seen in an outpatient anaesthetic clinic before surgery. This gives time for proper preoperative assessment, preoperative preparation and discussion of anaesthetic options.

Acute pain management plans

Individual plans for postoperative pain management should be formulated with the patient in the preoperative period. In the intraoperative period virtually all patients undergoing head and neck surgery receive intravenous opioids and, where possible, incisions should be infiltrated with a long-acting local anaesthetic such as bupivacaine 0.5 percent (maximum dosage 2 mg/kg) before the end of surgery. Early postoperative pain may be treated by intravenous opioid, often morphine in 2 mg increments every five minutes to a total of 10 mg, administered by the recovery nurse or doctor. Simple oral analgesia in adults, such as paracetamol 1 g six hourly and ibuprofen 400 mg six hourly, should be prescribed regularly. If oral administration is not possible, drugs may be given parenterally, by suppository or via a nasogastric tube. Initiation of analgesia by suppository (such as diclofenac 100 mg) towards the end of surgery is common, provided that the patient has consented to this.

More severe pain may be treated in the ward by regular dihydrocodeine 30 mg six hourly or morphine given by the oral or intramuscular route. If it is expected that the patient will require regular morphine, this is best given by patient-controlled analgesia (PCA) in which the patient receives a small dose of morphine intravenously on pressing a button. Preoperative instruction in the use of a PCA machine may be given by the anaesthetist, ward nurse or member of the acute pain team. The acute pain team consists usually of nurses, doctors and pharmacists and provides the lead in the generation of acute pain guidelines and management. The expertise of the acute pain team should be sought preoperatively in any patient in whom postoperative pain is likely to be difficult to manage, particularly those on preoperative opioids for medical or nonmedical reasons. Epidural analgesia is not suitable for surgery in the head and neck territory, but is useful to cover abdominal surgery when this is required to mobilize the bowel for major reconstructions. Acute pain guidelines usually detail the analgesic solution to be

used via the epidural route and the appropriate level of postoperative care.

CONSIDERATION OF VENOUS THROMBOEMBOLISM PROPHYLAXIS

Venous thromboembolism (VTE) is one complication among hospital inpatients and contributes to longer hospital stays, morbidity and mortality. Recent recommendations arise from the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy¹⁴ in 2004. Risk factors and conditions predisposing to VTE are:

- history of previous VTE;
- prolonged immobility or confinement to bed;
- lower limb, pelvic or abdominal operations;
- trauma particularly of pelvis or acute spinal injury;
- obesity;
- major medical illnesses, such as MI, ischaemic stroke, cardiac failure and acute respiratory failure;
- oestrogen use, such as oral contraception or hormone replacement therapy;
- cancer, especially metastatic adenocarcinoma
- age > 40 years;
- acquired hypercoagulable states, such as lupus anticoagulant and antiphospholipid antibodies, hyperhomocysteinaemia, dysfibrinogenaemia and myeloproliferative disorders;
- inherited hypercoagulable states, such as activated protein C resistance, protein C or S deficiency, antithrombin deficiency or prothrombin gene mutation.

All patients undergoing surgery should be placed in a risk stratification for VTE, with particular importance attached to identifying the high- and very high-risk patient. Expert haematological assessment is required when acquired or inherited hypercoagulable states are suspected.

- **Low risk.** Uncomplicated surgery in patients aged < 40 years with minimal immobility postoperatively and no risk factors.
- **Moderate risk.** Any surgery in patients aged 40–60 years, major surgery in patients < 40 years and no other risk factors, minor surgery with one or more risk factors.
- **High risk.** Major surgery in patients > 60 years, major surgery in patients aged 40–60 years with one or more risk factors.
- **Very high risk.** Major surgery in patients > 40 years with previous VTE, cancer or known hypercoagulable state.

An appropriate strategy for the prevention of VTE should be formulated for each patient and written guidelines should exist in each department. The preventative measures which have been shown to reduce the incidence

of VTE are early mobilization, compression elastic stockings, pneumatic intermittent calf compression which provides rhythmic external compression of the lower limb or calf to a pressure of 35–40 mmHg for ten seconds every minute, low-dose unfractionated heparin (LDUH) and low molecular weight heparin (LMWH). LMWH has the advantages over LDUH of once daily dosage and lower incidence of heparin-induced thrombocytopenia, but is more expensive. Comparative studies of LDUH and LMWH have shown a broadly similar efficacy but comparisons are hampered by the dosage and timing. LDUH is usually given as 5000 units 8–12 hourly and LMWH may be given in low doses (<3400 anti-Xa IU daily) or high doses (>3400 anti-Xa IU daily). High-dose LMWH appears to be associated with more surgical bleeding problems.

Unfortunately, little data exist on preventative measures in head and neck patients exclusively and data appropriate to groups may not benefit an individual patient. Surgery itself in the head and neck territory is considered low risk and there is the additional perceived problem of heparin causing minor, but surgically troubling, bleeding. This may cause difficulty during microscopic surgery or surgery near the skull base or brain, or result in an increase in incidence of wound haematoma.

A reasonable strategy for VTE prophylaxis in head and neck patients might be:

- **Low risk patients.** No specific prophylaxis other than early ambulation.
- **Moderate risk patients.** Either LMWH <3400 U daily, LDUH 12 hourly, compression elastic stockings or intermittent pneumatic compression. Each alone is better than no prophylaxis.
- **High risk patients.** LDUH eight hourly, or LMWH >3400 U daily plus compression stockings, or compression stockings and intermittent calf compression if anticoagulation considered inadvisable.
- **Very high risk.** LDUH eight hourly or LMWH >3400 U daily plus compression stockings and intermittent pneumatic compression.

CONSIDERATION OF SPECIAL REQUIREMENTS

Patients undergoing surgery in the head and neck region may lose, temporarily or permanently, sensation or motor activity in the distribution of the cranial nerves. Particularly important from a patient's perspective are the loss of communication arising from impairment of hearing, speech or vision, disabling sensation such as vertigo through vestibular dysfunction or alteration to normal activity such as eating, drinking or breathing. Patients who will be unable to speak postoperatively require a plan for communication, such as a bell to attract

attention, prepared cards indicating common needs, pen and paper or the use of hand-signals. For those patients undergoing laryngectomy, the preoperative period is the appropriate time to discuss voice reconstruction options and for the patient to meet the speech therapist and another patient who has undergone, and recovered from, similar surgery.

The disease process or nature of surgery may interfere with nutrition. Failure of adequate nutrition may lead to morbidity and mortality through infection, failure of wound healing and gross catabolism. Nutrition may be provided orally, through a nasogastric tube, via a percutaneous or open gastrostomy, via an open feeding jejunostomy or intravenously. The enteral route is superior in all regards to the intravenous route and should be used whenever possible. Poorly nourished patients require preoperative supplementation and there is some evidence that a week of enteral (but not parenteral) nutrition improves outcome. A feeding gastrostomy or jejunostomy can be placed in a planned manner at the time of extensive surgery to cover postoperative feeding.

Patients in whom the small or large bowel is required for surgical reconstruction of the upper GI tract may require bowel preparation with a low residue diet or intravenous fluids and laxatives.

PLANNING AND SCHEDULING OF THEATRE TIME AND POSTOPERATIVE CARE

The Confidential Enquiry into Postoperative Deaths (CEPOD)¹⁵ process identifies patients as being **elective** when the surgery can be planned for the convenience of the patient and surgeon, **scheduled** when admission will be prioritized within a few weeks of initial referral, **urgent** indicating an unplanned admission where resuscitation can be achieved before theatre and **emergency** in which surgery is required coexistent with resuscitation. A better scheme starts by indicating whether the patient is listed or unlisted, since the classification of CEPOD urgent or emergency is not always understood or useful.

The operating theatre list should be presented to theatre reception in the manner required within that hospital. Generally, a theatre list should contain the patients' name, hospital number, date of birth or age and planned surgery. The side of surgery should be recorded as left or right. Some hospitals use the Office for Population Censuses and Surveys (OPCS) or Read codes. The first patients on a list are generally children in ascending age, or shorter operations before longer ones or patients with diseases such as diabetes. Patients with latex allergy must be scheduled first to allow correct preparation of the operating theatre. Scheduling problems should be resolved by discussion between the surgeon, anaesthetist and theatre sister. Some patients will require a planned extended stay in Recovery, or admission to HDU/ITU. Generally, this will be for longer, major

procedures, when ventilation is required postoperatively, when the airway is at risk or if extended patient monitoring is required for cardiorespiratory disease. The bed should be booked as soon as surgery is planned for a particular date. Patients should know about the plans for the immediate recovery period (which may change) and may benefit from seeing the HDU/ITU preoperatively or talking to a nurse from the unit.

PREPARATION ON THE DAY OF SURGERY

It should be possible to estimate a provisional time of surgery and preparation aims to make certain that the patient is ready when the theatre calls for the patient. Most units use a form with tick boxes to cover the areas of baseline blood pressure, heart rate, weight, allergies, false or capped teeth, patient's wrist band present, consent form signed, notes and x-rays present, investigations present, blood cross-matched, time of last oral intake and details of premedication. The side and site of surgery should be indicated with an indelible marker by the surgeon who reviews the patient on the day.

Oral intake

Patients should not eat or drink prior to anaesthesia to reduce the risk of aspiration of gastric contents. The Association of Anaesthetists of Great Britain and Ireland recommends the following fasting periods which are now generally accepted:¹⁶

- six hours for solid food, infant formula or other milk;
- four hours for breast milk;
- two hours for clear nonparticulate and noncarbonated fluids.

There is no evidence that safety is improved by extending these fasting times. Some patients should not be left for long periods without fluids and consideration should be given to intravenous fluid administration. These include elderly or sick patients, children, those undergoing bowel preparation and breastfeeding mothers.

Medication

Generally, all regular medication should be given on the day of surgery unless specifically crossed off by the anaesthetist or surgeon. It is particularly important to give cardiac medication for angina, hypertension or arrhythmia. Diuretics are often omitted. Diabetic medication needs to be specifically addressed by the anaesthetist but generally tablets are not given on the morning of surgery and insulin given in either a reduced dosage subcutaneously with a covering intravenous infusion of 5 percent dextrose, or as a sliding scale. In a sliding scale the

patient receives a constant dextrose infusion such as dextrose 4 percent with saline 0.18 percent (with potassium 20 mmol in 1000 mL bag) at 100 mL/h and an insulin infusion adjusted one to two hourly according to blood glucose. There is some evidence that tight control of glucose to a range of 4–6 mmol/L is beneficial. Some oral medication, for example nitrates, may be prescribed as a transdermal preparation. Patients on oral steroids require an additional dose parenterally, either 50 mg hydrocortisone intravenously 8–12 hourly or an infusion of 150–200 mg/24 h.

KEY POINTS

- Consider day surgery where possible.
- Assess the risk of operation/anaesthesia.
- Moderate or severe cardiorespiratory disease requires medical/anaesthetic review.
- Routine preoperative tests are expensive and unnecessary.
- Valid, written consent required for most surgery.
- Consider venous thromboembolism prevention.
- Book HDU/ITU bed (if required) as soon as date of surgery known.
- Patients presenting for ENT surgery may be of either gender and of any age, with general health at any point between fit and moribund, for elective, scheduled or emergency surgery lasting between a few minutes and many hours. Perioperative care may need to be appropriate for minor surgery such as insertion of grommets as a day case or extensive head and neck surgery requiring intensive care.

Best clinical practice

- ✓ The patient should be directed into the correct pathway as soon as surgery is contemplated, and sufficient oral and written information given to inform the patient and initiate the consent process.
- ✓ Attendance at a preadmission clinic a few weeks before surgery allows a full history and examination to be taken, leading to the identification of any medical, anaesthetic or personal problems. This is particularly important when the interval between scheduling and admission for surgery is more than a few months.
- ✓ The requirement for specific preoperative blood tests, investigations and blood cross-matching should be agreed by the whole team and produced in a written

form which is available to doctors and nurses involved in preoperative preparation.

- ✓ Preoperative assessment of the problem patient by an anaesthetist, preferably the one who will be involved, is valuable and should be easy to arrange.
- ✓ Preoperative tests taken at preadmission should be reviewed before the admission for surgery so that abnormalities can either be treated in time or the patient rescheduled.
- ✓ Notify the acute pain team of any patient in whom postoperative pain control is likely to be difficult, particularly those with opioid dependency or on a drug withdrawal programme.

SEARCH STRATEGY

The data in this chapter are supported by a PubMed search using the key words difficult intubation, difficult airway, obstructed airway.

DEFINITIONS

The difficult airway is the clinical situation in which a practitioner experiences difficulty with adequate maintenance and/or protection of the airway. Three airway devices are in common use – the face mask, laryngeal mask and tracheal tube – and each offers a different level of airway protection and maintenance. A cuffed tracheal tube offers the highest level and for this reason is prominent in airway management plans in head and neck surgery.
